Pharmaceutical Division,
Haywards Heath, West Sussex RH16 1TP.
Telephone: (Haywards Heath) 0444 57911.

Distributed in the Republic of Ireland by
Bayer (Ireland) Limited,
Dun Laoghaire, Co. Dublin.
®Registered Trade mark of Bayer Germany

Bayer

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short-term infusion (5 ml/min to the patient in the recumben position); thereafter every 4 hours 200,000 KIU slowly i.v.

Important
Trasylol may in very rare cases (less tha 0.1%) cause hypersensitivity reactions.

Presentation
Ampoules of 100,000 KIU (Kallikrein Inactivator Units)
Ampoules of 200,000 KIU*
*not available in the Republic of Irelan

References

The citation of references sh[illegible] Reference Citation Recomm[illegible] [illegible]e Medical Section o[illegible] [illegible]opies of these recomm[illegible] Secretary, Medica[illegible] 7 Ridgmount Stree[illegible]

[illegible] of [illegible] are [illegible] in [illegible] list of works c[illegible] the end of [illegible] article, arranged in alpha[illegible] of authors' names. When references to two works by the same author occur, they are a[illegible] chronologically. More than two authors m[illegible] indicated in the text citation by the words 'e[illegible]', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. More than three authors may be indicated in the list of references by 'et al.'. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in order: the names and initials of up to three authors, the year of publication (in parentheses), the title of the paper, the abbreviated name of the Journal (as used by *Index Medicus* since 1971; if no abbreviation, give full title), the volume number (arabic numerals underlined) and the numbers of first and last pages of the article. A reference to a *book* should give, in order: the names and initials of up to three authors, compilers or editors, date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order: the names and initials of up to three authors of the contribution, the date of publication (in parentheses) and the title of the contribution; then, after the word 'In:', there should follow: name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the *original* language, with titles in Cyrillic and Greek alphabets transliterated.

Only in papers in which many and frequent references have to be ma[illegible] should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

*Constitute the Editorial Committee.

Whilst every effort is made by the publishers and editorial committee to see that no inaccurate or misleading opinion or statement appears in this Journal, they wish to make it clear that the opinions expressed in the articles and advertisements herein are the responsibility of the contributor or advertiser concerned. Accordingly, the publishers and the editorial committee and their respective employees, officers and agents accept no liability whatsoever for the consequences of any such inaccurate or misleading opinion or statement.

Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, Broadmead House, 21 Panton Street, London SW1.* Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the Journal unless rights are reserved before publication. Original illustrations must be securely packed and protected.

Business Communications should be sent to *John Wright & Sons Ltd, British Journal [illegible] Surgery, 42–44 Triangle West, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

Binding: Handsome cloth cases may be obtained for binding Vol. 65. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers who will also undertake the binding if desired.

Advertisements: All communications should be addressed to *Hexagon Publishing Co. Ltd, 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone 0727-60641: telex 888369).

Manuscripts
Two good quality plain paper photocopies of all written and tabular material should be submitted and the original retained by the author; such manuscripts will not be returned whether accepted or rejected. However, art and colour work will be returned at request. Double spacing should be used throughout. Each article should be accompanied by a summary, suitable for publication.

Illustrations and tables
Illustrations should also be submitted in duplicate clearly marked on the back to show number, orientation and author. Legends should be typed on a separate sheet. For halftones, unmounted glossy photographs or positive prints (*not* X-ray negatives or slides) are required. Colour prints should be accompanied by the original transparencies and a contribution to the cost of reproduction is always necessary. Drawings must be ready for reproduction; paper photocopies of line drawings are not acceptable. A leaflet giving details of the preparation of artwork is available from the publishers and *must* be consulted. Tables should be typed on separate sheets and should have a Roman identifying number plus a short descriptive heading. *All illustrations and tables must be referred to in the text.*

Presentation of statistics
Authors are reminded that:

a. The methods section of a paper should contain a mention of any statistical technique used. If the method is new or unfamiliar either a reference should be given or a description included as a brief appendix.

b. If alternative techniques could have been applied to the data, a short justification of the method is often appropriate.

c. In clinica[illegible]ls the confidence [illegible] to[illegible]nce limits of the results should be quoted, par[illegible] when formal statistical significance at the 5 pe[illegible]vel is only just reache[illegible]

d. Abbreviations for statistical terms should follow those used in *Documenta Geigy Scientific Tables*, 7[illegible] edition, 1970.

SI units
It is Journal policy to use SI units except for mea[illegible] ment of blood pressure, where mmHg is prefe[illegible] Authors should consult: Baron D. N., Brough[illegible] P. M. G., Cohne M. et al. (1974) The use of SI unit[illegible] in reporting results obtained in hospital laboratorie[illegible] *J. Clin. Pathol.* **27**, 590–597. Reprints are availab[illegible] from the British Medical Association, London.

Now: together: a unique [illegible] system and the best in skin care

SURGICARE System2

Trademark

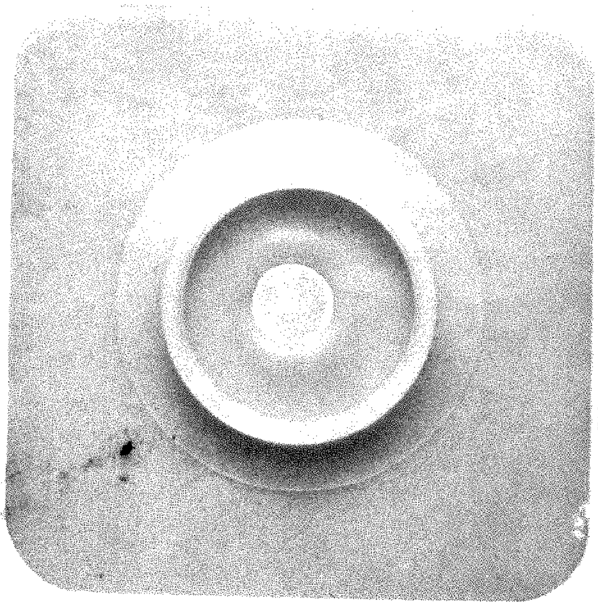
Surgicare™ System 2 saves the daily trauma of peeling off adhesive bags often resulting in irritation, soreness and discomfort. The Stomahesive™ with Flange can be left on the skin undisturbed for several days whilst pouches are replaced as often as necessary… so simply.

Kinder to the skin

Stomahesive™ with Flange may be used by patients who have experienced sensitivity reactions when using ordinary adhesives and karaya or where perspiration under the adhesive is a regular source of irritation and discomfort

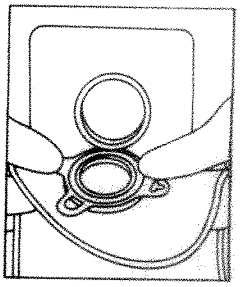
Unequalled comfort

The Stomahesive™ base will mould to irregular contours of the skin and is so easy to apply without wrinkling. Comfort is derived not only from the feel of Stomahesive™ against the skin but from the confidence that the appliance will be secure and leak free irrespective of the condition of the skin.



Avoids adhesive trauma

With the Stomahesive™ flange remaining undisturbed, pouches may be removed and replaced as necessary.



The colostomist, for example, may change pouches several times a day without the need to disturb the Stomahesive™ base and its flange.

A Century
of Service to
Surgery

Our past experience is your future safeguard, because we have brought all our expertise to bear on developing reliable instruments which complement specialist surgical skills. To achieve this, we have worked closely with the profession, researching and testing until exactly the right answers are found.
In fact our personal commitment and service is yet another reason why, for a hundred years, our instruments have set the standard by which others are judged.

Fundiplication Forcep

The principle of fundiplication is to restore an effective valvular mechanism to the cardiooesophageal junction by wrapping the mobilised fundus of the stomach around the cardia which is thereby enclosed within a sleeve of stomach. This manoeuvre is facilitated by the fundiplication forcep which firmly grasps the fundus in order to surely draw it behind the cardia into its desired new position

A curious occipital polyp

M. GABER*

SUMMARY

Muscles which lose their attachments are uncommon. During development this normally occurs in certain muscles, e.g. the muscles of the face and epicranius; these muscles lose their skeletal connections before migration. In the case presented here a muscle in the occipital region had lost its attachment and formed a peculiar swelling.

Case report

A 6-year-old girl presented with an occipital pedunculated swelling 5 cm long (*Fig.* 1) which moved up and down during mastication (*Fig.* 2). No other movements of the face, neck or the tongue caused such a movement. The swelling was present at birth and continued to grow slowly with the child.

The swelling was excised. During dissection a muscle was seen attached to the external occipital protuberance. On section the muscle was found to be inserted into the skin at the apex of the swelling, causing corrugations of the skin (*Fig.* 3).

Histological section showed striated muscle with a tendinous end in the centre of fibro-fatty tissue. Nerve fibres were also seen (*Fig.* 4).

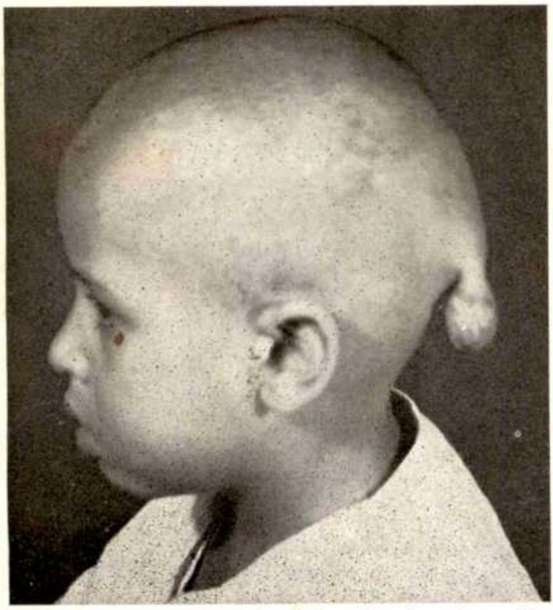

Fig. 1. The patient with the head shaved to show the swelling.

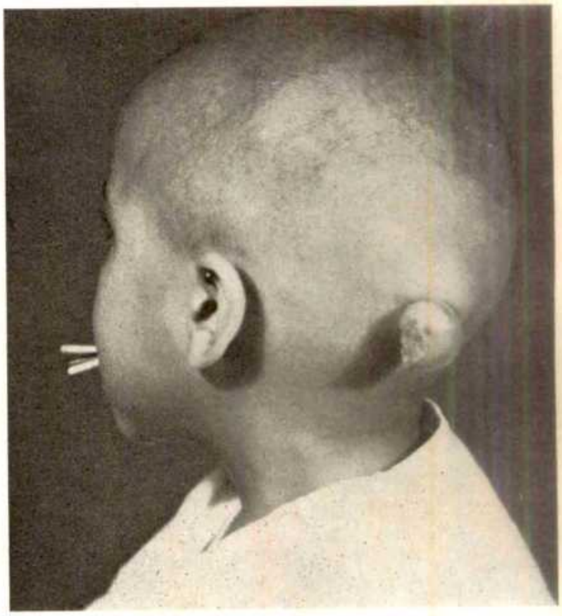

Fig. 2. Showing the movement of the swelling on mastication.

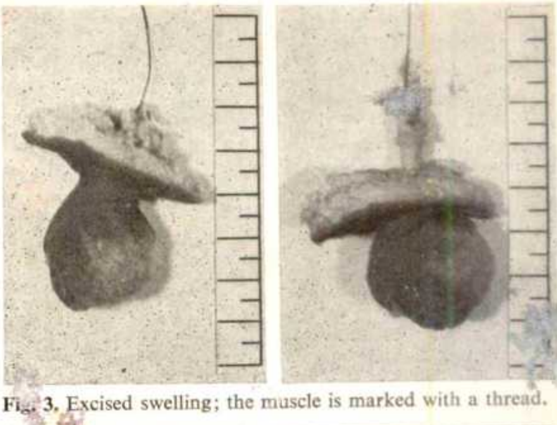

Fig. 3. Excised swelling; the muscle is marked with a thread.

---

* Senior Lecturer, Azhar University, Cairo.
Correspondence to: Charing Cross Hospital, London.

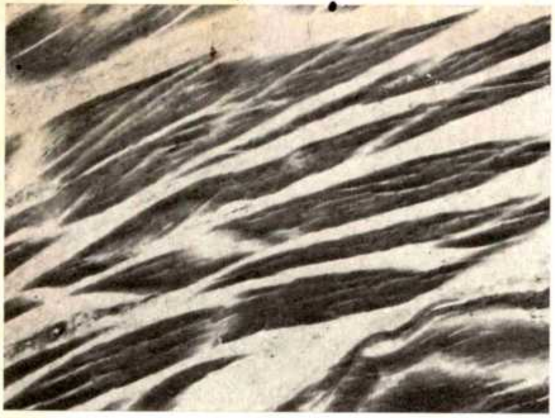

Fig. 4. Histological section showing the muscle. (HE. × 60.)

Discussion

The muscle mentioned in this case could be the transversus nuchae muscle, which is present in 25 per cent of the population. It takes origin from the external occipital protuberance and frequently is inserted with the auricularis posterior muscle. It is supplied by the occipital division of the posterior auricular branch of the facial nerve. The muscle in this case may have had a common innervation with the buccinator muscle, which is also supplied by the facial nerve. If so, this would explain the movement of the swelling during mastication.

Muscles of the tongue develop in the occipital region before migration; the possibility of the muscle mentioned in this case being a detached part of this group of muscles is remote.

Spinal epidural abscess presenting as acute abdomen in a child

G. W. TYSON, A. GRANT AND W. E. STRACHAN*

SUMMARY
Spinal epidural abscess is seldom encountered in children and rarely occurs in the absence of spinal pain. A case is described in which a child with a thoracic epidural abscess presented with abdominal rather than spinal pain. Thoracolumbar radicular inflammation and visceroparietal reflexes initiated by a 'spinal ileus' probably produced the symptoms and signs of acute intra-abdominal disease. Consideration of intraspinal disease is advisable in all cases of acute abdomen which exhibit atypical features.

MOST paediatric surgeons have little experience with spinal epidural abscesses since these lesions account for only 0·2–1·2 of every 10 000 general hospital admissions (Baker et al., 1975) and less than 1·5 per cent of the reported cases involve children (Davidson and Zajac, 1978). Fortunately, the early signs and symptoms of this disease usually direct the surgeon's attention to the spine before permanent motor and sensory paralysis supervenes. Spinal pain is the most important initial complaint (Messer et al., 1977) and was mentioned by all 20 patients reported by Heusner (1948), by all 39 reported by Baker et al. (1975) and by all 49 reported by Hancock (1973). In addition, local tenderness was elicited by spinal percussion in 90–100 per cent of these cases. Early diagnosis may be almost impossible when local spinal pain is inconspicuous or absent (Ashby, 1977), when toxic epiphenomena divert attention from subtle signs of neurologic dysfunction and when the patient is an acutely distressed and uncooperative child. The following case is unusual in that it involved a child in whom a history of spinal pain was not obtained and the clinical presentation was that of acute intra-abdominal disease.

Case report

A 7-year-old girl developed malaise, anorexia and dysuria 6 days before the eventual hospital admission. She subsequently complained of aching over the anterior aspect of both thighs. Two days before admission she developed constant central abdominal pain and intermittent vomiting. She had a single, normal bowel movement during this 6-day period. At no time did she complain of back pain.

On examination the child appeared toxic and anxious. The blood pressure was 100/60 mmHg, the heart rate 130/min and the oral temperature 38·4 °C. The entire abdomen was distended and resonant. There was generalized tenderness and guarding, but these signs were more prominent in the right lower quadrant. Only mild tenderness was elicited on digital rectal examination. Bowel sounds were normal in pitch but decreased in frequency.

The haemoglobin was 10·2 g/dl, the white blood cell count 16×10^9/l and the erythrocyte sedimentation rate (Wintrobe) 58 mm/h. Urinalysis demonstrated 3 leucocytes per high-powered field. Urine culture was sterile. Serum electrolytes, urea and creatinine were all normal. Abdominal X-rays revealed gaseous distension of both the large and small bowels with several fluid levels.

The patient underwent laparotomy on the night of admission in order to exclude appendicitis. A large volume of non-purulent, free peritoneal fluid was encountered (which subsequently proved to be sterile). The entire bowel was dilated but otherwise normal. The appendix was not grossly inflamed. The retroperitoneal tissues also appeared normal. Needles were inserted into the psoas muscles but no pus could be aspirated.

The following morning the patient was afebrile. She continued to complain of bilateral anterior thigh pain and developed cutaneous hyperaesthesias over these areas. Both groins were tender to palpation. Late in the day she became incontinent of urine. On the morning of the second postoperative day the nurse noted that the child did not move her legs when she was placed on the bed pan.

Examination at that time disclosed a flaccid paraplegia. Deep tendon reflexes were difficult to obtain and plantar reflexes could not be elicited. Hypoalgesia to pin-prick was present to the level of the umbilicus (T10). Because of nuchal rigidity and headache, a lumbar puncture was performed at the L3–4 interspinous space. Viscous, yellow cerebrospinal fluid was obtained, but the flow soon ceased. Yellow–green pus (10 ml) was aspirated from the epidural space as the needle was withdrawn. A Gram stain demonstrated clumps of Gram-positive cocci. *Staphylococcus aureus* resistant to penicillin was cultured from both the spinal fluid and the epidural pus. The cerebrospinal fluid had a glucose content of 1·2 mmol/l (normal 2·8–5·6) and contained 22 polymorphonuclear leucocytes and 14 lymphocytes per cubic millilitre.

The patient was given intravenous gentamicin and cloxacillin and was transfered to the neurosurgery service at Plymouth General Hospital. The midthoracic spinous processes were found to be tender to palpation. Plain X-rays of the entire spinal column showed no signs of osteomyelitis. A cisternal myelogram demonstrated a complete subarachnoid block at the T4 level. Less than 6 h after she was first noted to be paraplegic, the patient underwent a T4 laminectomy. More than 20 ml of pus were evacuated from the epidural space. Rubber catheters (8 Fr.) were inserted rostrally and caudally into the spinal canal and were brought out through a separate skin incision. The laminectomy incision was closed primarily.

The epidural space was irrigated every 6 h with a solution containing cloxacillin (1 g/100 ml) which was instilled through the catheters. The catheters were removed after 5 days. The patient received flucloxacillin (1 g/d) parenterally for 10 days and then orally for 4 weeks. A myelogram on the seventh postoperative day was normal.

The patient gradually regained lower extremity strength and bowel and bladder continence. Two months after laminectomy she was fully ambulatory, and motor, sensory and reflex examinations were normal.

Discussion

No spinal cause of acute abdominal pain in children was encountered in a recent clinical series reported by Jones (1976) or in an earlier one reported by Winsey and Jones (1967). However, Cope (1972) notes that abdominal pain is a frequent symptom of vertebral osteomyelitis in children and he advocates inspection and palpation of the spine in those cases of abdominal pain in which diagnosis remains in doubt. The relatively high incidence of laparotomy in spinal diseases that present atypically with major abdominal complaints probably indicates that this suggestion is

often overlooked (Sullivan and Symmonds, 1964; Watkin, 1970).

Suspicion should be raised by even minor symptoms that are not typical of intra-abdominal disease. For example, our patient complained of anterior thigh pain and paraesthesias, which were probably due to inflammation of upper lumbar nerve roots. She also had a persistent headache, which is common with spinal epidural abscess (Heusner, 1948; Baker et al., 1975) but is infrequent with intra-abdominal disease (Winsey and Jones, 1967). Urinary incontinence (or retention) often adumbrates motor and sensory paralysis, which may occur abruptly and then be only partially reversible. In addition to spinal tenderness, examination during the pre-paralytic phase of spinal cord compression often discloses hyperactive reflexes in the lower extremities and extensor plantar reflexes. Diagnosis and treatment during the pre-paralytic phase are of critical importance since the degree of residual functional impairment is directly related to the degree and duration of the preoperative neurological deficit (Heusner, 1948).

Spinal epidural abscess and intra-abdominal sepsis may occasionally coincide since infection may spread haematogenously via veins that connect the epidural space with the thoracoabdominal wall and with the retroperitoneum (McLaurin, 1967). In addition, an epidural abscess may extend through intervertebral foramina and along spinal nerves to produce a perinephric abscess (Stammers, 1938). In this case, however, laparotomy excluded these possibilities. Therefore, the patient's signs and symptoms were probably referable to disturbances in the innervation of the abdominal wall and viscera. Abdominal pain, rigidity and local tenderness may be caused by inflammation of the lower thoracic nerve roots which supply the abdominal wall (Sullivan and Symmonds, 1964). These signs and symptoms are more commonly due to visceroparietal reflexes which are caused by visceral dysfunction. Intraspinal disease may not only enhance these reflexes (Ashby, 1977) but may also produce a 'spinal ileus' which initiates them (Watkin, 1970). This syndrome of colicky abdominal pain associated with gaseous distension of the bowel and variable changes in bowel sounds may be encountered in a variety of spinal lesions, including fractures, herniated intravertebral discs and spinal cord infarcts (Watkin, 1970). The pathogenesis of this syndrome remains unclear, but probably involves an acute imbalance between the sympathetic and vagal innervations of the bowel (Morton et al., 1960).

Toxic dilatation of the colon in salmonella colitis and inflammatory bowel disease

PHILIP F. SCHOFIELD, B. K. MANDAL AND A. G. IRONSIDE*

SUMMARY

Toxic dilatation of the colon may be due to inflammatory bowel disease, either ulcerative colitis or Crohn's disease of the colon, but recent experience has shown that infective colitis due to salmonella can produce this complication. We present 13 cases with toxic dilatation (9 inflammatory bowel disease and 4 salmonellosis) and outline the diagnostic features and treatment in these patients. It is important to distinguish salmonellosis at an early stage because, whilst toxic dilatation in inflammatory bowel disease is an absolute indication for surgical treatment, cases with this complication due to salmonellosis may be treated conservatively in the majority of instances.

FOR many years gross dilatation of the colon due to inflammation was thought to be a complication which only occurred in ulcerative colitis (Marshak et al., 1950; Brooke and Sampson, 1964). More recently, the complication has been recognized in Crohn's disease of the colon (Turnbull et al., 1970).

Mandal and Mani (1976) demonstrated that salmonella infection commonly produces invasive changes in the colon, and confirmation of their findings was quickly reported from South Africa (Appelbaum et al., 1976) and from Yugoslavia (Radsel-Medvescek et al., 1977). This invasive change may, at times, be severe enough to produce toxic dilatation of the colon (Boyd, 1976; Mandal and Mani, 1976). The purpose of this paper is to report our experience of this complication in both infective and non-infective inflammatory bowel disease.

Patients and methods

During the years 1974–7, 13 patients presented, either to the regional infectious diseases department for the North-west or to the surgical unit which carries out the operative management, with toxic dilatation of the colon. All the patients included in this series were severely ill with colitis and radiologically had gross dilatation of the colon. In the adults the diameter of the transverse colon varied between 8 and 12 cm and in the one infant in the series (*Case* 13) the dilated transverse colon measured 5 cm. Of these cases, 4 were due to ulcerative colitis, 5 to Crohn's disease of the colon and 4 to salmonellosis. Ten of these patients presented to the infectious diseases unit (3 with ulcerative colitis, 4 with Crohn's disease and 3 with salmonellosis) while the other 3 patients, including 1 case of salmonella infection, presented to the surgical unit. All 9 patients with non-infective inflammatory bowel disease (4 with ulcerative colitis and 5 with Crohn's disease) required surgical treatment by subtotal colectomy and ileostomy. One of the 4 patients with toxic dilatation due to salmonella infection required colostomy but the other 3 patients recovered with medical treatment. *Tables I* and *II* show the clinical and investigatory features in all 13 patients. Since toxic dilatation of the colon due to salmonella infection has only recently been reported, we present the 4 patients in our series in more detail.

Case 10: A 19-year-old man was admitted to the infectious diseases unit with a 7-day history of frequent vomiting and diarrhoea, but the stool contained no blood. He had lost weight during his illness and on admission he looked ill and was pyrexial. The abdomen was grossly distended and tympanitic with scanty bowel sounds and there was slight rebound tenderness in the left iliac fossa. The spleen was palpable. He was clinically dehydrated and biochemical studies showed a sodium level of 117 mmol/l, potassium 2·9 mmol/l, chloride 83 mmol/l and blood urea 5·15 mmol/l. His haemoglobin was 13·3 g/dl and the white cell count was 13·6 × 10^9/l (neutrophils 87 per cent). The straight film of the abdomen revealed gross gaseous distension of the colon. Sigmoidoscopy showed inflamed, oedematous mucosa with absent vascular pattern, and rectal biopsy later revealed oedema of the lamina propria with vascular congestion and haemorrhages. Stool culture grew *Salmonella typhimurium*, phage type I, var. 5.

The patient was treated with intravenous fluid replacement and received systemic chloramphenicol, in view of the possibility of salmonella septicaemia, but this was not confirmed. Over the next 4 days the patient's condition improved steadily with gradual lessening of his abdominal distension and diarrhoea. Following recovery, he has been reviewed periodically for 3 years as an outpatient and has had no further bowel problem.

Case 11: A 56-year-old man was admitted to the infectious disease unit with a 15-day history of profuse diarrhoea, commencing soon after a Spanish holiday. He was having watery diarrhoea six to ten times a day without blood or mucus.

On admission, he was febrile and looked ill. The abdomen was grossly distended and tympanitic, with slight rebound tenderness in the right iliac fossa.

A plain X-ray of the abdomen revealed marked gaseous distension of the colon. Biochemistry showed normal serum electrolytes and a blood urea of 2·66 mmol/l. The haemoglobin was 12 g/dl and the white cell count was 14·200 × 10^9/l (neutrophils 61 per cent). Sigmoidoscopy revealed a generally hyperaemic and granular mucosa and biopsy later showed oedema and an increase in the chronic inflammatory cell population of the lamina propria but no crypt abscess formation. Stool culture grew *Salmonella enteritidis*. The man's symptoms and abdominal distension settled slowly over the next 2 weeks. He received no antibiotic therapy.

Barium enema examination several days after admission still showed some colonic dilatation with an abnormal and irregular mucosal pattern in the descending colon and on the left side of the transverse colon, indicative of ulceration.

On outpatient follow-up there were no bowel symptoms and the results of barium enema examination returned to normal.

Case 12: A 47-year-old female was admitted with increasingly severe watery diarrhoea and colicky abdominal pain for 2 weeks following a holiday in Spain. She was treated at home with antibiotics and three stool cultures sent by her family doctor were negative. On admission she looked ill and dehydrated with a tachycardia of 140/min and blood pressure of 80 mm systolic. Her abdomen was grossly distended and tender.

Serum electrolyte estimation confirmed salt depletion. Plain X-ray showed total colonic gaseous distension, most marked in the right and transverse colon. Sigmoidoscopy showed a red inflamed mucosa with absent vascular pattern but no contact bleeding.

Because of the abdominal distension and marked signs of peritoneal irritation, laparotomy was performed immediately following rehydration with intravenous fluids. The colon was grossly dilated with some thickening in the right and transverse colon with a gangrenous area in the mid-transverse colon 1 cm in diameter. The small bowel was normal. The devitalized area on the transverse colon was exteriorized through a separate

incision and a colostomy opened and sutured to the skin. The following day stool culture confirmed salmonella group B and the patient was given a course of chloramphenicol. She recovered steadily and was discharged 18 days after the operation.

Three months later barium studies showed a normal colon and the colostomy was then closed. The patient has remained well for 2 years.

Case 13: A 15-month-old male infant was admitted to the infectious diseases unit with a 10-day history of diarrhoea, not containing any blood. He was not dehydrated and his diarrhoea settled soon after admission. *Shigella sonnei* was isolated from his faeces and initially his appeared to be a case of resolving Sonne dysentery, but 7 days after admission there was a recurrence of fever and severe diarrhoea with rapid distension of the abdomen. Straight X-ray of the abdomen revealed multiple fluid levels in the small intestine and gross distension of the colon.

Further stool cultures now yielded *Salmonella typhimurium*, presumably due to cross-infection, thus explaining the severe recurrence of symptoms. The child gradually improved over the next few days with intravenous fluid therapy and he has remained quite well since.

Differentiating features

History and examination

It may be difficult to distinguish acute colitis due to salmonella infection from that due to non-infective inflammatory bowel disease. Both conditio diarrhoea of similar severity, leading to electrolyte depletion with tachycardia tension. The history of a recent Mec holiday or a history of less than 2 weeks' suggestive of salmonella infection whereas matory bowel disease the recent history longer and often there is a history of previo

Blood in the stool may be a striking featu cases of salmonella infection, but more us is absent from the stool (Mandal and M In this study, none of the 4 cases of salmon blood in the stool but bleeding was us inflammatory bowel disease cases.

When toxic dilatation is present the a distended, and in the salmonella infectio this series tenderness was always present was absent in several cases of inflammat disease. Two cases of the latter did hav abdominal masses.

Sigmoidoscopy

The appearances in both ulcerative c salmonella colitis showed diffuse inflammat ment of the rectum with spontaneous oedema and pus, and therefore did n distinguish the two conditions. In Crohn the proctitis may be of similar type but may be relatively spared or contain linear this was found in several cases. Thus, in sigmoidoscopy had a useful discriminator identifying Crohn's disease in several of th

Biopsy

This is quite a useful procedure in diff salmonella colitis from inflammatory bo (Day et al., 1978); however, it played rela part in the urgent management of these pa toxic dilatation because a decision had t regarding urgent surgery before the biops processed.

Stool culture

Repeated stool cultures are of considerable i in all patients presenting with bloody diarr of a persistent nature. Early specimens negative if the patient has received anti happened in *Case* 12.

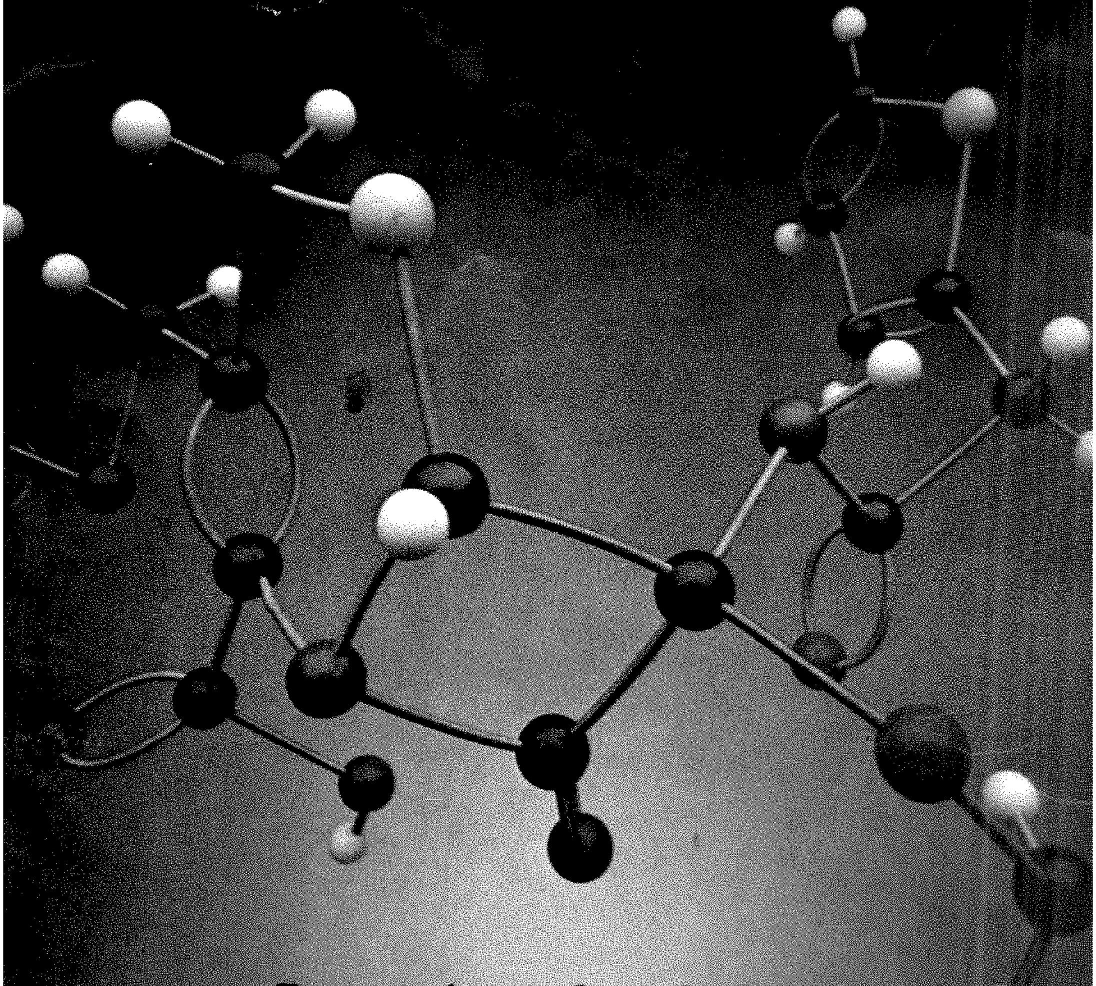
MSD announces
the discovery of

Mefoxin®

Cefoxitin sodium, MSD

INJECTION

First of the cephamycins

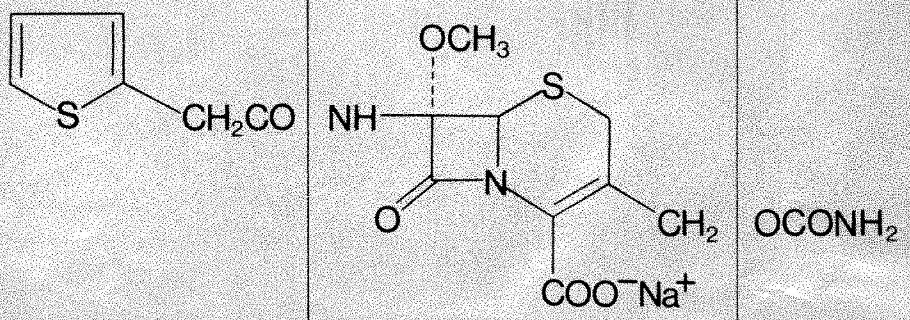


A new class of antibiotics

'Mefoxin' is derived from cephamycin C, a naturally occurring antibiotic substance produced by *Streptomyces lactamdurans*. This naturally occurring antibiotic has been modified in the MSD Research Laboratories to enhance its therapeutic usefulness.

Prescribing information overleaf

'Mefoxin' has a unique molecular structure offering outstanding clinical benefits and a specific clinical profile.



Thienylacetyl side-chain:

enhances activity against Gram-positive pathogens

Cephamycin nucleus:

provides bactericidal activity against a wide range of pathogens, Gram-negative in particular. 7α-methoxy group protects against β-lactamase degradation

Carbamoyloxy side-chain:

protects antibiotic from being metabolised

▼Prescribing information

Indications

'Mefoxin' is a broad-spectrum bactericidal antibiotic indicated for the treatment of infections caused by susceptible strains of Gram-positive and Gram-negative pathogens both aerobic and anaerobic.

'Mefoxin' has been clinically effective not only in infections due to antibiotic-sensitive organisms, but also in infections due to organisms resistant to one or more of the following antibacterial agents: penicillin, ampicillin, carbenicillin, tetracyclines, erythromycin, chloramphenicol, cephalosporins, kanamycin, gentamicin, tobramycin, and sulphamethoxazole-trimethoprim.

Many Gram-negative pathogens are resistant to penicillins and cephalosporins through the action of the β-lactamases which are produced by these pathogens. 'Mefoxin' is remarkably stable in the presence of these bacterial β-lactamases, both penicillinases and cephalosporinases. Hence, the clinical efficacy of 'Mefoxin' extends to many infections caused by such pathogens.

'Mefoxin' is indicated for the treatment of the following infections caused by sensitive bacteria:
Peritonitis and other intra-abdominal and intrapelvic infections, female genital tract infections, septicaemia, urinary tract infections, respiratory tract infections, bone and joint infections, and skin and soft-tissue infections.

'Mefoxin' is indicated for adjunctive therapy in the surgical treatment of infections including abscesses, infection complicating hollow visceral perforations, cutaneous infections, and infections of serous surfaces, whether caused by aerobes, mixed aerobes and anaerobes, or anaerobes.

Microbiology

'Mefoxin' is active *in vitro* against:

Aerobic bacteria

Gram-positive cocci including: *Staphylococci* (including coagulase-positive, coagulase-negative, and penicillinase-producing strains); Group A beta-haemolytic streptococci (*Streptococcus pyogenes*); Group B beta-haemolytic streptococci (*Streptococcus agalactiae*); *Streptococcus pneumoniae* (*Diplococcus pneumoniae*); other streptococci (except group D streptococci including enterococci, most strains of which are resistant, e.g. *Streptococcus faecalis*). *Gram-negative cocci including*: *Neisseria gonorrhoeae* (including penicillinase-producing strains); *Neisseria meningitidis*. *Gram-negative rods* (*facultative anaerobes*) *including*: *Escherichia coli*; *Klebsiella pneumoniae*; Klebsiella spp.; *Proteus mirabilis*; *Proteus* (indole positive); *Proteus vulgaris*; *Proteus rettgeri*; *Proteus morganii*; *Haemophilus influenzae*; *Serratia marcescens*; Providencia spp.; Salmonella and Shigella spp.

Anaerobic bacteria

Gram-positive cocci including: Peptococcus spp.; Peptostreptococcus spp.; Micro-aerophilic streptococcus. *Gram-positive rods including*: *Clostridium perfringens*; Clostridium spp.; Eubacterium spp.; *Propionibacterium acnes*. *Gram-negative cocci including*: Veillonella spp. *Gram-negative rods including*: *Bacteroides fragilis*; *Bacteroides melaninogenicus*; Bacteroides spp. (including both penicillin-susceptible and penicillin-resistant strains); Fusobacterium spp.

'Mefoxin' is active against some strains of the following bacteria: *Acinetobacter calcoaceticus* var *anitratum* (*Herellea vaginicola*); *Acinetobacter calcoaceticus* var *lwoffi* (*Mima polymorpha*); *Alcaligenes faecalis*; Citrobacter spp. and Flavo-bacterium spp.; Enterobacter spp.

'Mefoxin' is not active against Pseudomonas, most strains of enterococci and many strains of *Enterobacter cloacae*.

Dosage and administration

'Mefoxin' may be administered intravenously or intramuscularly. (See reconstitution directions for each route below.) Dosage and route of administration should be determined by severity of infection, susceptibility of the causative organisms, and condition of the patient.

Therapy may be started while awaiting the results of susceptibility testing.

Dosage: The usual adult dosage is 1 g or 2 g of 'Mefoxin' every eight hours. (See chart.)

In adults with renal insufficiency, an initial loading dose of 1 g or 2 g may be given. After a loading dose, the following recommendations for *maintenance dosage* may be used as a guide.

Usual adult dosage

Type of infection	Dose	Frequency	Total daily dosage
Uncomplicated	1 g	Every 8 hours (occasionally every 6 hours)	3 g (4 g)
Moderately severe or severe	2 g	Every 8 hours (occasionally every 6 hours)	6 g (8 g)
Infections generally needing antibiotics in higher dosage	3 g (2 g)	Every 6 hours (Every 4 hours)	12 g

Maintenance dosage of 'Mefoxin' in adults with reduced renal function

Renal function	Creatinine clearance (ml/min)	Dose	Frequency
Mild impairment	50-30	1-2 g	Every 8-12 hours
Moderate impairment	29-10	1-2 g	Every 12-24 hours
Severe impairment	9-5	0.5-1 g	Every 12-24 hours
Essentially no function	<5	0.5-1 g	Every 24-48 hours

In the patients undergoing haemodialysis, the loading dose of 1 to 2 g should be given after each haemodialysis, and the maintenance dose should be given as indicated in the table above.

Intravenous administration: reconstitute 'Mefoxin' with Water for Injection BP. 1 g is soluble in 2 ml. Although 'Mefoxin' is very soluble, for intravenous use it is preferable to add 10 ml of Water for Injection BP to the 1 g vial or the 2 g vial. Shake to dissolve and then withdraw entire contents of vial into syringe.

For direct intravenous injection, 'Mefoxin' may be slowly injected into

Outstanding clinical benefits

Wide-ranging activity against Gram-negative and Gram-positive pathogens, anaerobes as well as aerobes.

Unusually high resistance to β-lactamase degradation.

Highly active against *Bacteroides fragilis* and strains of *E. coli*, Serratia, Klebsiella spp. and Proteus spp. (including indole positive strains) resistant to other antibacterial agents.

Offers high levels of active antibiotic in the body.

A record of relative safety comparable to the penicillins.

Prime indications include:

– Peritonitis, and other intra-abdominal and intrapelvic infections.
– Female genital tract infections
– Septicaemia
– Skin and soft tissue infections
– Bone and joint infections
– Urinary tract infections
– Respiratory tract infections (e.g. inhalation pneumonia)

Specific clinical profile

'Mefoxin' is exceptionally valuable wherever Gram-negative pathogens and anaerobes are involved in mixed infections. When mixed infections are suspected, therapy may be started while awaiting the results of susceptibility testing.

Mefoxin®

Cefoxitin sodium, MSD Injection

First of the cephamycins

the vein over a period of 3 to 5 minutes or may be given through the tubing when the patient is receiving parenteral solutions.

An intermittent intravenous infusion of 'Mefoxin' may be employed when large amounts of fluid are to be given. However, during infusion of the solution containing 'Mefoxin' it may be advisable temporarily to discontinue administration of any other infusion solution at the same site (by using an appropriate IV infusion set).

A solution of 'Mefoxin' may also be given by continuous intravenous infusion (see below for compatibility and stability).

Intramuscular administration ONLY
Reconstitute 'Mefoxin' 1 g with 2 ml of Water for Injection BP or 0.5% or 1% lignocaine hydrochloride (without adrenaline) solution. 'Mefoxin' is given by deep injection into a large muscle mass. Avoid injection into a blood vessel.

Compatibility and stability
A solution of 'Mefoxin' in Water for Injection BP may be added to the following solutions: 0.9% Sodium Chloride Injection BP, 5% or 10% Dextrose Injection BP, Dextrose and Sodium Chloride Injection (5% 0.9%, 5% 0.45%, or 4.3% 0.18%), Lactated Ringer's Injection USP, 5% Dextrose in Lactated Ringer's Injection, 5% or 10% invert sugar in water, 10% invert sugar in saline solution, 4.2% Sodium Bicarbonate Injection BP, M/6 Sodium Lactate Injection BP.

'Mefoxin', as constituted to 1 g/10 ml with Water for Injection BP, Water for Injection BP preserved with parabens or benzyl alcohol, 0.9% Sodium Chloride Injection BP or 5% Dextrose Injection BP, maintains satisfactory potency for 24 hours at room temperature, for 96 hours under refrigeration, and for 13 weeks in the frozen state.

'Mefoxin' can be administered concomitantly with such antibiotics as gentamicin, tobramycin, carbenicillin or amikacin. When 'Mefoxin' is administered with another antibiotic, they should not be mixed in the same syringe.

Contra-indications
'Mefoxin' is contra-indicated in persons who have shown hypersensitivity to cefoxitin. In the absence of clinical experience, 'Mefoxin' should not be administered to patients who have shown hypersensitivity to cephalosporins.

Precautions
There is some clinical and laboratory evidence of partial cross-allergenicity between cephamycins and other β-lactam antibiotics: penicillins, and cephalosporins. Severe reactions (including anaphylaxis) have been reported with most β-lactam antibiotics.

Before therapy with 'Mefoxin', careful inquiry should be made concerning previous hypersensitivity reactions to β-lactam antibiotics. 'Mefoxin' should be given cautiously to penicillin-allergic patients.

Any patient who has demonstrated some form of allergy, particularly to drugs, should receive antibiotics cautiously. If an allergic reaction to 'Mefoxin' occurs, the drug should be discontinued.

The total daily dosage should be reduced when 'Mefoxin' is administered to patients with transient or persistent reduction of urinary output due to renal insufficiency (see 'Dosage and administration'), because high and prolonged serum antibiotic concentrations can occur from usual doses.

Interference with laboratory tests
A false-positive reaction to glucose in the urine may occur with reducing substances but not with the use of specific glucose oxidase methods.

Use in pregnancy
Use of the drug in women of childbearing potential requires that the anticipated benefit be weighed against possible hazards. Reproductive and teratogenic studies have been performed in mice and rats and have revealed no evidence of impaired fertility or harm to the foetus due to 'Mefoxin'. There are no controlled studies with 'Mefoxin' in pregnant women.

Nursing mothers
'Mefoxin' is excreted in human milk.

Infants and children
Pending the outcome of clinical trials in progress, the conditions for use of 'Mefoxin' in infants and children remain to be defined.

Side effects
'Mefoxin' is generally well tolerated. Side effects rarely require stopping treatment and [illegible]

The next best thing to levitation

Imagine how much easier and efficient operations would be if there were no operating table to get in the way.

If you could simply suspend the patient firmly in mid-air in precisely the correct position.

And if you could change that position with a minimum of fuss or disturbance to patient.

Well Thackray believe that after years of research and development, they've designed the next best thing to levitation.

The Thackray International 5. The International 5 general table has a five section top instead of the more conventional four.

Why five? Because it makes anatomical sense to have table top articulations corresponding to the four major points of articulation of the body.

It's an advantage that soon becomes obvious in operation when minimal patient repositioning is required.

The advantages of the International 5 do not stop at five.

There's the unique hydraulically operated control system giving smooth, fail-safe control of the table's amazing repertoire of movements.

The built in X-ray facilities and ability to accept a host of accessories including orthopaedic attachments.

The International 5. It one-up's every other operating table.

Fig. 1. Plain X-rays of toxic dilatation of the colon in *Case* 6. *a*, Early changes with gas at the splenic flexure. *b*, The position 24 h later with total colonic and some small bowel distension.

Blood culture
It is customary in the infectious diseases unit to obtain routine blood cultures from all patients presenting with diarrhoea, as transient bacteraemia is a fairly common event in salmonella enterocolitis and a positive report may be forthcoming before the stool culture. This procedure was not helpful in the present cases.

Radiology
Abdominal radiographs in erect and supine positions showed gross dilatation of the colon (*Fig*. 1). There were no radiological differences between the inflammatory bowel disease and salmonella cases. Furthermore, in the resolving salmonella cases, barium enema examination sometimes demonstrated ulceration that was difficult to differentiate from ulcerative colitis or Crohn's disease of the colon, but repeat barium studies 3–6 months after the acute attack showed a return to a normal colonic outline.

Treatment and results
In patients with severe colitis, a period of intensive intravenous therapy was usually necessary to correct dehydration and restore the circulation. The cases were monitored very closely at this time by repeated pulse and blood pressure readings, abdominal girth measurement, abdominal X-rays and urea and electrolyte estimations.

During this period the salmonella cases tended to behave differently, with rapid progressive improvement in all aspects, even if there was toxic megacolon on X-ray. In the one salmonella case in which laparotomy was necessary, simple colostomy was carried out and the colon was spared because of different and more favourable appearances at operation. In the inflammatory bowel disease group of cases, progressive rapid improvement was not seen during the period of close observation. Several cases were stationary and several deteriorated in some aspects during this period and all 9 cases came to operation (*Table III*).

Table III. OPERATIVE FINDINGS AND TREATMENT

Case no.	Colon involved	Perforation	1st op.	2nd op.	Pathology
1	Total	Walled-off colon	SCI	AP	Crohn's
2	Total	No	SCI	AP	Crohn's
3	Total	No	SCI	—	Crohn's
4	Total	Walled-off ascending colon	SCI	IR	Crohn's
5	Total	No	SCI	AP	Crohn's
6	Total	No	SCI	—	CUC
7	Total	No	SCI	—	CUC
8	Total	Gangrene at splenic flexure, no perforation	SCI	AP	CUC
9	Total	No	SCI	AP	CUC
12	Right and transverse	Gangrene mid-transverse colon; no perforation	TC	CC	Salmonella

SCI, Subtotal colectomy and ileostomy; IR, ileorectal anastomosis; AP, abdominoperineal excision of rectum; CUC, chronic ulcerative colitis; TC, transverse colostomy; CC, close colostomy.

The mortality from persisting with medical treatment in toxic dilatation due to inflammatory bowel disease is so high that it was our policy to advocate operation as soon as this complication developed. The mortality of excisional surgery in this situation is less, and has been reported variously to be between 14 and 30 per cent (Goligher, 1975). Our surgical policy has been to use subtotal colectomy with ileostomy if there is no abscess formation, resorting to ileostomy and colostomy if there is a walled-off perforation (Turnbull et al., 1970). It was not considered necessary to use this latter procedure in any of the patients in this series, though in retrospect it might have been used in *Case* 1 who became severely ill with septicaemia after subtotal colectomy with ileostomy.

All the patients in the series are alive and well.

Discussion

It is usually stated in communications dealing with inflammatory bowel disease, either ulcerative colitis or Crohn's disease, that an infective cause should be excluded. We would certainly agree with this viewpoint, but our experience indicates that this can be very difficult (Mandal, 1974).

It should be accepted that many cases of acute diarrhoeal illness are caused by specific infections, among which salmonella infections are prominent. As a result, most clinicians would only admit cases of acute diarrhoeal illness into hospital under conditions of strict isolation.

It has been emphasized recently that salmonella infections may cause a severe colitis with profuse bloody diarrhoea showing sigmoidoscopic appearances and barium enema changes indistinguishable from inflammatory bowel disease (Mandal and Mani, 1976).

The present series goes further and demonstrates that toxic dilatation of the colon, accepted as one of the worst complications of inflammatory bowel disease, may also be caused by salmonella infection. The series showed that cases due to salmonella tended to resolve with medical treatment. On the other hand, the cases due to inflammatory bowel disease failed to improve rapidly with medical treatment but instead tended to deteriorate, so that surgical removal of the colon quickly became necessary.

In retrospect, the differentiation has been made to appear easy, but it was not so in the clinical situation at the time and it should be stressed that the decision to operate should be made entirely on the developing clinical picture and not solely on the presence or absence of a salmonella organism. Furthermore, the isolation of a salmonella organism in a case of acute colitis does not end the diagnostic difficulty because of the occasional occurrence of an associated salmonella infection in cases of inflammatory bowel disease. This is indeed a doctor's dilemma, both from a diagnostic and therapeutic viewpoint.

It is concluded from this series that salmonella infection needs to be considered in the differential diagnosis throughout the entire spectrum of severity of acute colitis, including cases of toxic dilatation.

In the assessment and management of these cases, our experience has convinced us of the value of a team with medical and surgical facilities and with experience of the whole range of infective and non-infective inflammatory bowel disease.

A clinical trial of endolymphatic therapy in malignant melanoma: interim report of the progress of the Medical Research Council trial

MRC WORKING PARTY ON ENDOLYMPHATIC THERAPY IN MALIGNANT MELANOMA*

SUMMARY

This report presents the interim results of the MRC trial on the treatment of Stage I melanoma of the lower limb by endolymphatic therapy.

Over a 10-year period a group of 146 patients has been entered into the trial. Although total recurrence rates were not significantly affected by endolymphatic therapy, recurrence in the lymph nodes was largely prevented. More patients in the standard treatment group needed the more major procedure of block dissection.

The survival rates for the endolymphatic and standard treatment groups did not differ significantly.

THE encouraging clinical results in the treatment of melanoma by the use of endolymphatic therapy (Jantet, 1958, 1962; Jantet et al., 1964) stimulated interest in this technique. The method was similar to that used in diagnostic lymphography except that a radioactive isotope was bound to the diagnostic agent to irradiate regional lymph nodes involved with tumour. Animal studies also showed definite advantages for endolymphatic therapy compared with controls (Edwards, 1966; Edwards et al., 1966).

A controlled clinical trial was subsequently sponsored by the Medical Research Council in 1966. This trial was designed to compare two methods of management in patients with stage 1 melanoma of the lower limb, either by excision of the primary tumour followed by endolymphatic therapy to the regional nodes or by excision of the primary tumour followed by other treatment, not involving endolymphatic therapy, such as immediate or delayed block dissection according to the discretion of the clinician responsible.

Patients and methods

Patients aged between 15 and 70 years with a clinical diagnosis of malignant melanoma of the lower limb were eligible for admission to the trial, except those patients: (*a*) with clinical involvement of the regional lymph nodes; (*b*) with signs of distant spread on general clinical examination or on a chest radiograph; (*c*) with widely scattered satellite lesions on the same limb as the primary lesion which could not be removed by surgery at the same time as the primary lesion; (*d*) who were found to be pregnant; (*e*) who were referred specifically for endolymphatic therapy.

Allocation to the two treatment groups

The main centres involved in the trial were St Thomas' Hospital, London, the University Hospital of Wales, Cardiff, Mount Vernon Hospital, Northwood, the Postgraduate Medical School, Hammersmith, and the Royal Infirmary, Glasgow. Patients were entered into the trial from these centres having met the conditions of entry, including histological confirmation of the diagnosis of invasive malignant melanoma by the local pathologist. Patients were randomly allocated to either 'endolymphatic therapy' or 'therapy by existing methods' using the sealed-envelope technique (randomization being separate for each centre).

Subsequently, the local pathologist would send one stained and one unstained section of the primary melanoma to each of the pathologists comprising the melanoma reference panel. All three members of the panel had to agree that the sections showed invasive malignant melanoma. If the diagnosis was not accepted the patient was excluded from the trial. (The members of this panel were Dr O. C. Lloyd, Professor S. J. de Navasquez and Dr I. W. Whimster. Professor N. F. C. Gowing joined the panel later in place of Professor Navasquez.)

After random allocations detailed clinical information regarding each patient was recorded (analysis of which will be presented at a later date).

Treatment

Standard treatment: Treatment in the 'existing methods', standard or non-endolymphatic therapy group consisted of various schemes of management. Some surgeons followed excision of the primary lesion by block dissection of regional nodes in all cases. Others awaited clinical evidence of involvement before performing dissection. The essential difference was that in this group endolymphatic therapy was not used.

Technique of lymphography: It was decided that no centre should enter the trial until experience in the relevant technique had been gained by the appropriate clinician. The suggested technique for endolymphatic therapy was agreed by the Working Party and circulated to all centres involved in the trial. This technique was developed at St Thomas' Hospital (Edwards and Kinmonth, 1968; Edwards, 1969).
The first isotope combination used in the trial was ^{131}I-lipiodol. Subsequently it was found that ^{32}P-lipiodol was probably more

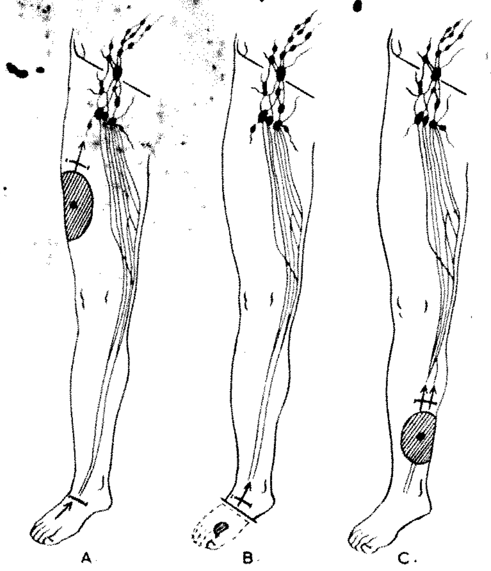

Fig. 1. Melanoma of the lower imb: primary growth shaded and site of injection of radioactive material indicated by arrows.

effective and this was used from 1968. The clinical advantages of ^{32}P-lipiodol as compared with ^{131}I-lipiodol may be summarized as follows:

1. Increased maximum penetration of β-particles of 8 mm as compared with 2 mm for ^{131}I.

2. Pure β-emitter, reducing any radiation hazard to personnel in theatre.

3. Increased half-life of 14 days as compared with 8 days for radio-iodine.

Owing to faster metabolic turnover of lipiodol in the lungs as opposed to the lymph nodes there would be potentially less β-radiation dosage to the lungs with ^{32}P than with the use of radio-iodine.

With ^{131}I-lipiodol the aim was to achieve a dose of 35 mCi at the time of the injection and with ^{32}P, a dose of 6 mCi. This dosage was calculated on the basis of experimental and clinical studies evaluating the histological effects of varying dosages. The dose was decided on the basis of the observation that destruction of lymph nodes with small metastases occurred with regularity. The actual β-dose in rads was estimated by using the β-emitter dosimetry formula (Hine and Brownell, 1956).

By direct measurement of radioactivity on excised nodes, and by confirming the uniform distribution of the isotope by the histological effect and autoradiography, the use of this formula has shown the β-dose to reach 100 000 rad with the dosage quoted for clinical use (Edwards and Kinmonth, 1967).

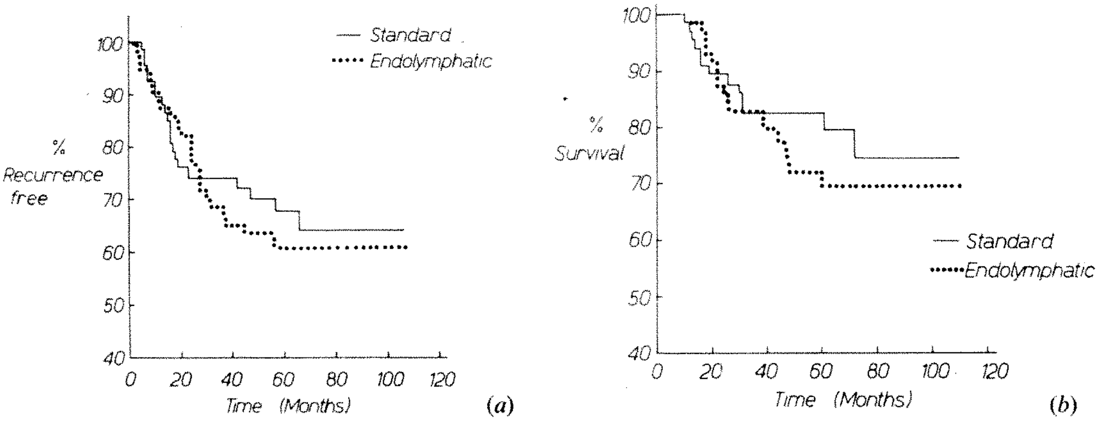

Fig. 2. *a*, Actuarial percentage recurrence-free curves for standard treatment ($n = 72$) and endolymphatic treatment ($n = 74$). *b*, Actuarial percentage survival curves for standard ($n = 72$) and endolymphatic ($n = 74$) treatment.

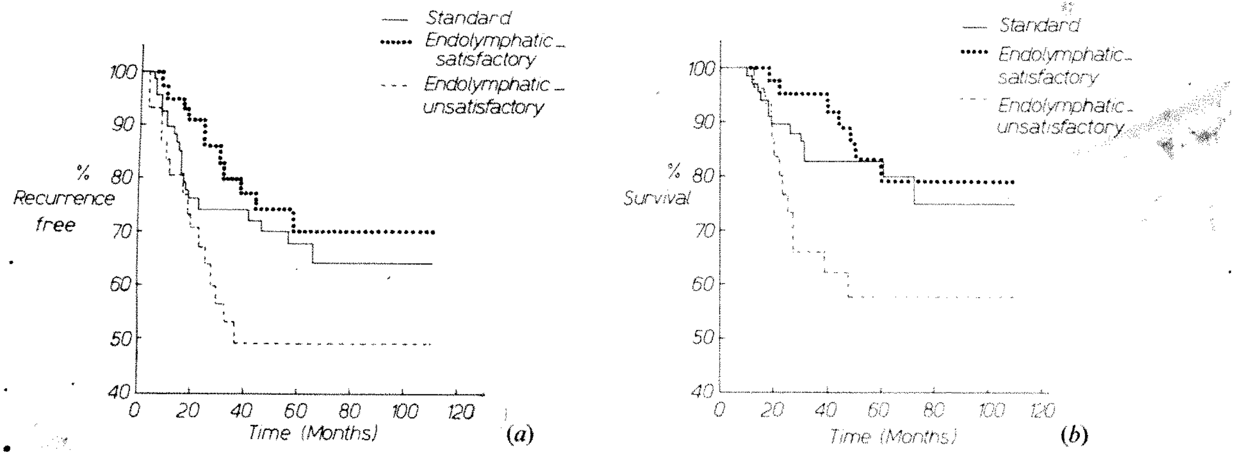

Fig. 3. *a*, Actuarial percentage recurrence-free curves for standard treatment ($n = 72$) and for 'satisfactory' ($n = 42$) and 'unsatisfactory' ($n = 32$) endolymphatic treatment. *b*, Actuarial percentage survival curves for standard treatment and 'satisfactory' and 'unsatisfactory' endolymphatic treatment (numbers in each group as for *a*).

The following factors were regarded as particularly important:

1. Wherever possible, the injection was proximal to the site of the primary lesion (*Fig.* 1).

2. For growths in the thigh, anterior leg and foot a lymphatic on the dorsum of the foot was injected, provided that the primary melanoma site did not lie across the pathway of the lymphatics. A 10 per cent aqueous and autoclaved solution of Patent Blue was injected between the toes to demonstrate the lymphatics and also around the melanoma site in those cases in which multiple injections were necessary.

3. For growths on the back of the leg (in the drainage area of the small saphenous vein) where lymph might drain via the popliteal fossa, an attempt was made to inject a lymph trunk proximal to the primary site. If this was unsuccessful the usual dorsal pedal injection was made.

4. Lugol's iodine was given orally 3 days before the injection of radio-iodine.

5. Cannulation of the lymphatic was made with a no. 30 needle, swaged on to polyvinyl tubing (Rutt et al., 1964) that was connected to a syringe containing the radioactive material.

6. The injection was made slowly, taking no less than 10 min for each millilitre, to avoid extravasation of the radioactive material through the walls of the lymphatic.

7. Screening and protection. The sterile syringe, with a measured amount of radioactive lipiodol, was brought to the theatre in a lead container and transferred and carefully connected to the lymphangiogram set in the autoinjector, surrounded by 2·0 cm of lead. The remaining lipiodol in the syringe and tubing was measured so that the total dose injected was known.

8. Radiographs were taken early in the course of the injection and the initial cases were also monitored with a modified Geiger counter.

Post-injection treatment: Radiographs of the limb, pelvis and lumbar regions were taken at the end of the injection and 24 and 48 h later to show if any extravasation had occurred and to demonstrate the state of the regional nodes. Radiographs of the pelvic areas were taken in three projections, antero-posterior, lateral and oblique. If the nodes showed filling defects suggesting tumour deposits, then surgical extirpation of these nodes was required. The patients remained in the study, however, in the endolymphatic therapy group.

A total body scan was done 48 h after injection. All urine was saved for 5 days and the radioactivity assayed daily; blood samples were also taken for assay.

White cell blood counts were made at 5 days and 21 days after injection.

At subsequent reviews, white cell counts and radiographs of the pelvis and abdomen were taken and correlated with the clinical assessment of the lymph nodes. The surgeon has to decide whether to excise lymph nodes should metastases of significant size show on lymphadenograms. It was suggested that an interval of at least 4 weeks should elapse before excision to allow the radioactivity to subside to a safe level. In view of the longer half-life of ^{32}P, a longer period of about 6 weeks was suggested before block dissection.

Follow-up

Patients were seen monthly for the first 3 months, then every 3 months for 2 years and thereafter 6-monthly. Questionnaires were completed on each occasion which recorded details of any complications, such as lymphoedema or local skin reactions, or progress of the disease, such as enlargement of nodes needing block dissection. Note was also made of subsequent pregnancy or the onset of the menopause, the occurrence of other forms of malignant disease and the period spent in hospital or away from work. A chest radiograph was taken 1 year after treatment.

If a patient declined later treatment, block dissection for instance, he was kept in the trial and counted as a failure of treatment, a special note being made of the refusal to enable these cases to be withdrawn if necessary from the final assessment of the trial. A failed attempt at endolymphatic therapy was also counted as a failure of initial treatment, the patient being kept in the trial and a note made.

A second treatment by endolymphatic therapy was given if considered necessary. In both groups of patients the addition of general or local treatment was not contraindicated if there was recurrence. The surgeon or radiotherapist was allowed to treat any subsequent recurrence in the way he thought best.

Results

Entry to the trial was terminated on 30 November 1974, and by then 171 patients had been entered (*Table I*). This report has been compiled from information received on the state of the patients to 1 March 1975. In 16 patients (9·4 per cent of the total entered) the diagnosis of malignant melanoma was not confirmed histologically, and these patients were withdrawn from the trial. A further 9 patients (5·3 per cent of the total entered) were withdrawn for other reasons, i.e. stage 2 melanoma (1 patient), presence of secondaries (2 patients), presence of second primary melanoma (1 patient), disagreement amongst the pathology panel (3 patients), failure to give the allocated treatment (1 patient) and incorrect entry of a referral for endolymphatic therapy (1 patient). Thus, of 171 patients entered into the trial, 146 (85·4 per cent) were eligible for inclusion, and the analyses reported here are based on information received about them (*Table I*). Seventy-two patients (49·3 per cent of those eligible for inclusion) received standard therapy, 74 (50·7 per cent) received endolymphatic therapy.

In 135 patients (68 standard therapy, 67 endolymphatic therapy) treatment of the primary lesion was by wide excision and skin grafting. The average area excised was 36 cm^2. The deep fascia was left intact in 95 patients (48 standard, 47 endolymphatic) and the skin graft taken from the contralateral limb. Nine patients (3 standard, 6 endolymphatic) were treated by amputation, usually when the melanoma occurred in the subungual site (and the digit was amputated). For 2 patients (1 standard, 1 endolymphatic) the treatment of the primary lesion was not recorded.

There were no important differences between the standard therapy group and the endolymphatic group as regards age and sex distribution, the history, description and area of the primary lesion, the presence of satellite lesions, previous treatment and the occurrence of pain, pruritus and significant trauma.

The actuarial percentage recurrence-free and survival rates at yearly intervals from 1 to 5 years are shown for standard and endolymphatic therapies in *Table I*; the corresponding survival curves are shown in *Fig.* 2. Comparison of the recurrence-free and survival curves for the two therapies, using the log rank test, indicates no significant difference between them ($P = 0·67$ and $P = 0·43$ respectively).

Soon after the start of the trial, a significant failure rate in the application of endolymphatic therapy was apparent. This was stated quite simply as 'not satisfactorily administered' in the record form, owing to failure to identify lymphatics or to cannulate them even when identified. The high failure rate was also reflected in the measurements and radiographic studies; the dose administered was low, and on radiographs, the lymph nodes were not satisfactorily opacified. Some patients were given endolymphatic therapy a long time after treatment of the primary (in some cases there was over a year's delay). On further inquiry, it seemed that these were stage 2 melanomas having treatment for lymph nodes obviously involved with tumour. After consideration, it was decided that

Table I: ACTUARIAL PERCENTAGES OF PATIENTS RECURRENCE-FREE AND SURVIVING AT YEARLY INTERVALS UP TO 5 YEARS FROM ENTRY TO THE TRIAL ACCORDING TO THERAPY

		Withdrawn for			Actuarial percentage									
					Recurrence-free at (yr)					Surviving at (yr)				
Treatment group	Total entered	Negative or equivocal histology	Other reasons*	Total eligible	1	2	3	4	5	1	2	3	4	5
Standard	83	6	5	72	89·6	74·2	74·2	70·1	67·7	97·0	89·3	82·3	82·3	82·3
Endolymphatic: satisfactory	—	—	—	42	95·2	85·4	80·0	74·1	70·2	100·0	95·2	95·2	83·0	78·8
Endolymphatic: unsatisfactory	—	—	—	32	80·4	63·3	49·0	49·0	49·0	96·7	76·4	66·0	57·3	57·3
Endolymphatic: total	88	10	4	74	89·0	76·2	65·1	63·3	61·1	98·6	87·3	82·9	72·1	69 7

* Includes 1 stage 2 melanoma, 2 patients with secondaries, 3 patients regarding whom the pathological panel disagreed on diagnosis, 1 patient with a second primary melanoma, 1 patient given the 'wrong' treatment and 1 patient referred for endolymphatic therapy incorrectly entered in the trial.

Table II: SITE OF PRESENTATION OF INITIAL RECURRENCE

Group	No. of patients	Recurrence in nodes	%	Recurrence in skin*	%
Standard methods	69	13	19	4	6
Endolymphatic: satisfactory	48	1	2	7	16
Endolymphatic: unsatisfactory	25	3	12	8	32

* Recurrence in skin includes the primary site and distal areas.

the endolymphatic therapy group be subdivided to isolate those patients whose treatment was unsatisfactory.

The administration of endolymphatic therapy was regarded as unsatisfactory for any of the following reasons:

1. Stated as not satisfactorily administered on record form (9 patients).
2. Dosage too low (less than 4 mCi ^{32}P or less than 25 mCi ^{131}I) (3 patients).
3. The interval between surgery and endolymphatic therapy exceeded 3 months (13 patients).
4. The paravertebral lymph nodes were not filled (12 patients).

Five patients included under group 1 also fall into another of the groups 2 to 4.

Thus, 32 patients (43·2 per cent of those receiving endolymphatic therapy) were considered to have been treated unsatisfactorily. In the remaining 42 patients, the endolymphatic therapy was considered satisfactory. The actuarial recurrence-free and survival rates for these two groups are also shown in *Table I*. The corresponding curves are shown in *Figs*. 3*a* and *b* respectively, together with the curve for the standard therapy group. The recurrence-free and survival rates are significantly higher in the 'satisfactory' group than in the 'unsatisfactory' group (log rank test, $P = 0{\cdot}024$ and $P = 0{\cdot}014$ respectively). Similarly, both the recurrence-free and survival rates are higher in the standard therapy group than in the 'unsatisfactory' group, though only the latter is statistically significant at $P = 0{\cdot}05$ (log rank test, $P = 0{\cdot}091$ and $P = 0{\cdot}047$ respectively). There are no significant differences between the standard therapy group and the 'satisfactory' group.

The presentation of initial recurrence is of particular interest and is shown in *Table II*, for recurrences before March 1974. There appears to be a different pattern in the mode of recurrence in the different treatment groups; in the endolymphatic group the initial recurrence tends to be in the skin rather than in the lymph nodes whereas in the standard therapy group lymph node recurrence is high.

Discussion

In view of the enthusiasm of the participants at the onset of the trial, it has been disappointing that only a relatively small number of patients are available for analysis, even though the trial was continued for almost 10 years. Some points of interest have, however, emerged.

1. When treated adequately by meticulous attention to the primary lesion, melanoma of the lower limbs is not nearly as serious a disease as has been previously described. Standard treatment methods give a 5-year actuarial recurrence-free rate of 67 per cent when treatment is applied to stage 1 melanoma.
2. Endolymphatic therapy significantly reduced the recurrence rate in the lymphatic system, although skin recurrence was higher in this group. The interpretation of this trend may indicate that prevention of lymphatic relapse seems to have allowed relapses elsewhere to be seen first, but without appreciably reducing the total relapse rate. Probably a more likely explanation is that destruction of small metastases in nodes was effected by endolymphatic therapy at the price of a lymphatic blockage effect causing in-transit metastases to develop in the skin. Mild lymphatic oedema is occasionally seen after endolymphatic therapy.
3. The major factor that could influence the results in all the groups is the pathology of the primary tumour. All lesions have been broadly classified as *invasive malignant melanoma*, but this classification is now recognized as too wide. The clinician can recognize certain macroscopic pathological types that can be regarded particularly with foreboding, and further work by the pathologist must aim at determining the characteristics of these 'bad' lesions. We would conclude that a further, more detailed, pathology survey is indicated and these results will be presented in the final analysis of the trial.
4. A number of patients in the standard treatment group required regional node dissection as part of

this treatment, either initially or subsequently. This is a more major procedure for the patient than an endolymphatic injection. On the other hand, endolymphatic injection requires specialized skill which may not be readily available in all centres.

Royal College of Surgeons of England

The first joint meeting of the Royal College of Surgeons of England and the American College of Surgeons is to take place at the Queen Elizabeth Hall in London from 12 to 14 March 1979. The English College is responsible for the detailed planning of the meeting which is expected to attract at least 500 American surgeons, and the meeting is of course of special interest to their colleagues in England.

'The Generality of Surgery' is the theme of the meeting and this has been chosen to illustrate the conviction that, notwithstanding the development of specialties, there is a large area of common ground shared by most surgeons at some time in their professional life. In planning the programme, therefore, almost all the time has been allotted to plenary sessions in the hope that surgeons working on many different specialties and subspecialties can be brought together in a way that the advent of specialist societies with their own meetings has made increasingly rare. The particular interests of dental surgeons and anaesthetists are included in the symposium on 'Trauma and Intensive Care'. Other symposia are entitled 'The Growing Edge of Surgery' (with sections on Endoscopy, Modern Trends in Diagnostic Imaging and Implants), 'Early Carcinoma of the Breast', 'Abdominal Cancer—is major therapy worthwhile?', 'Trauma and Intensive Care', 'Parathyroid Disease' and 'Wound Healing and Suture Materials'. Each symposium has a British convener and at least one major American contributor. The meeting will conclude with addresses delivered by Dr William H. Muller jun., Chairman of the Board of Regents of the American College of Surgeons, and by Lord Smith, Past President of the Royal College of Surgeons of England.

A programme for ladies and other family members, a social programme and a trade exhibition have also been arranged.

Surgical and Faculty Fellows of the Royal College of Surgeons of England are invited to apply for further particulars to:

Joint RCS/ACS Meeting 1979
Conference Services Limited
43 Charles Street
Mayfair
London W1X 7PB
(Telephone 01-499 1101)

In the event of places remaining available, applications from Fellows of other Colleges may be considered shortly before the meeting.

An abdominal extraperitoneal approach for the difficult orchidopexy

PETER F. JONES AND FREDERICK H. BAGLEY*

SUMMARY

An abdominal extraperitoneal approach is described for use in patients who have a severe degree of incomplete descent of the testicle. In 86 such operations, the testicle was placed in the scrotum in 85. The approach allows certainty of diagnosis in cases of anorchia and it is helpful when orchidopexy has to be combined with a herniotomy in infancy.

THE operation of orchidopexy has changed very little since the first detailed description of Arthur Dean Bevan of Chicago in 1899. An operation which has remained in general use for so long must be effective, but there are, nevertheless, a number of patients in whom successful orchidopexy is not achieved by this technique in one operation. Bevan himself recognized this when he wrote in 1903:

> I have found by experience that in operating on cases in which the testicles are not palpable I could not, by the method described, free the testicle sufficiently to bring it into the scrotal pocket without tension. The tense structures which prevented reduction were the spermatic vessels not the vas.

Most surgeons would agree that it is the freeing of the testicular vessels which is the crucial part of the operation, and in operating on impalpable testicles it is essential to do this retroperitoneally, above the deep inguinal ring. To achieve this, attention has generally been focused on enlarging the deep inguinal ring. Davison (1911) advised division of the posterior wall of the inguinal canal and Gross (1953) advocated dividing the conjoint tendon laterally and the inferior epigastric vessels medially to improve the access to the retroperitoneal space and to straighten the line of the testicular vessels (*see* legend to *Fig.* 7). Using these manoeuvres, surgeons have achieved surprisingly different results. Bevan (1929), after 30 years of experience, failed to place the testicle in the scrotum in only 3–4 per cent of his patients; the failure rate of others has varied from 1·3 per cent (Gross and Replogle, 1963) and 3 per cent (Persky and Albert, 1971) up to 21 per cent (Firor, 1971) and 40 per cent (Dougall et al., 1974).

These figures suggest that the procedure still presents an appreciable problem, even if the deep inguinal ring is opened widely, and it is well known that the exploration for an abdominal testicle through this approach can be very taxing. In these difficult cases we believe that a better approach is to expose the deep inguinal ring from above, through an abdominal incision that will also allow an extensive retroperitoneal dissection.

The extraperitoneal approach was suggested for inguinal hernia repair by Cheatle in 1921, and 3 years later Paul La Roque of Richmond, Virginia, suggested an abdominal transperitoneal approach for orchidopexy. It was not until 1957 that Florence drew attention to the excellent exposure of the testicular vessels which he had obtained whilst carrying out an extraperitoneal dissection of the lower end of the ureter through a lower midline incision: later he deliberately explored 7 maldescended testicles in this way. Since then others (Bourque, 1961; Lipton, 1961; Jacobson, 1966) have reported enthusiastically on orchidopexy performed through a lower midline or Pfannenstiel incision, with extraperitoneal dissection.

Over the past 4 years we have become convinced of the value of an abdominal extraperitoneal approach for orchidopexy but we have used a muscle-splitting incision (Fowler, 1900; Weir, 1900).

Technique

1. Because the operation uses an abdominal incision it is helpful if the anaesthetist provides adequate muscular relaxation.

2. The skin incision is placed appreciably higher than usual and runs medially in a skin crease from a point internal to the anterior superior iliac spine to a point just short of the midline (*Fig.* 1). External oblique is split in the line of its fibres to reveal the linea semilunaris. This is picked up and incised horizontally with a knife, the anterior rectus sheath being split medially with scissors. Laterally, the muscular bellies of internal oblique and transversus abdominis are also split with the help of scissors and then the two index fingers are inserted through all layers and the muscle-split completed (*Fig.* 2).

3. Retractors are inserted and the transversalis fascia opened to reveal the surface of the peritoneum. If the lower retractor is now lifted the processus vaginalis will be seen entering the deep inguinal ring, and often the testicle is seen at this level, lying within the processus vaginalis (*Fig.* 3).

4. The processus vaginalis is picked up, gently separated from the deep ring and rotated slightly. This reveals the testicular vessels and the vas deferens adhering to the posterior aspect of the processus: these structures can be gently separated from the processus by sharp and blunt dissection. When this process is complete, the processus (i.e. the neck of the inguinal hernial sac) should be divided and tied off flush with the peritoneal cavity, the ligature being held long (*Fig.* 4).

5. Gentle traction on the testicular vessels and the vas then delivers the testicle from the inguinal canal: the testicle is usually tethered at its lower pole by connective tissue strands, and these are divided. Once freed, the testicle is brought out of the wound and the retroperitoneal dissection is commenced by pulling upwards and forwards on the ligature on the hernial neck; this reveals the retroperitoneal space, which can be further opened up by retraction (*Fig.* 4). The testicular artery and veins are freed by progressive division of the restraining strands of 'lateral spermatic fascia'. This freeing-up process can be carried towards and sometimes up to the lower pole of the kidney. A similar freeing of the vas deferens is carried medially, down into the pelvis. Following this extensive dissection the spermatic cord has usually lengthened sufficiently to allow the testicle to be placed at the level of the mid-scrotum (*Fig.* 5). If this is so, the retroperitoneal dissection is complete and the next step is described in paragraph 8.

6. Sometimes the processus vaginalis is seen entering the deep ring but there is no sign of the testicular vessels or vas. The testicle may then be found adherent to the posterior surface of the peritoneum 1–2 cm or more above the deep ring. If the neck of the hernial sac is divided and opened up this allows the

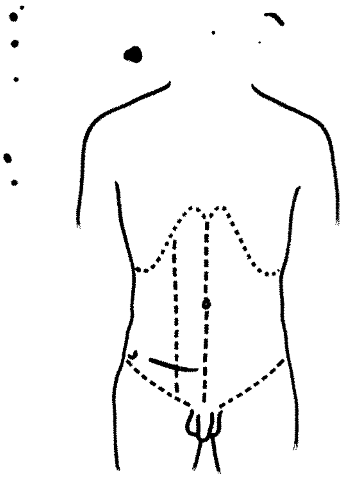

Fig. 1. The line of incision.

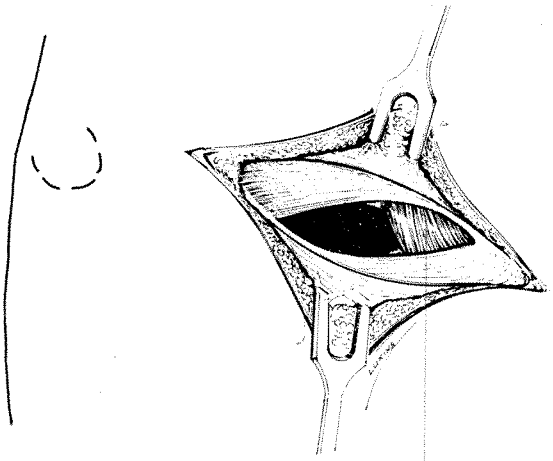

Fig. 2. The incision is held open to show the two layers of muscle which are split: first, external oblique and secondly, the internal oblique/transversus layer. The incision into the anterior rectus sheath reveals the lateral edge of rectus abdominis. (In *Figs.* 2–6 the patient is viewed as if from the foot of the operating table. The position of the right anterior superior iliac spine is shown as a dotted semicircle.)

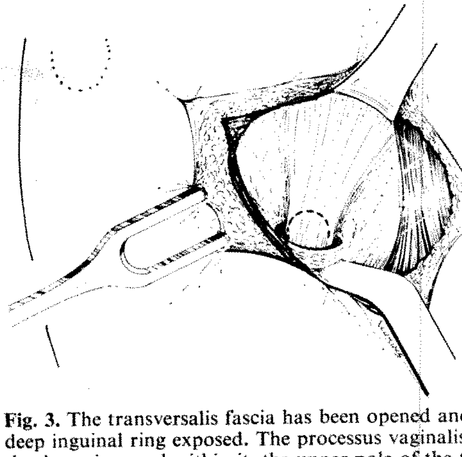

Fig. 3. The transversalis fascia has been opened and the deep inguinal ring exposed. The processus vaginalis enters the deep ring, and within it, the upper pole of the testicle can be seen (dotted line).

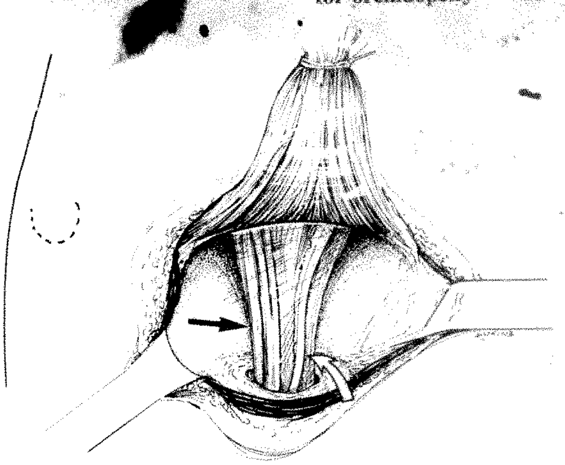

Fig. 4. The inguinal hernial sac has been dissected off the testicular vessels (black arrow) and the vas (white arrow), and a ligature has been placed around its neck. Traction on the neck of the sac opens up the retroperitoneal space and allows freeing of the vessels and vas to commence.

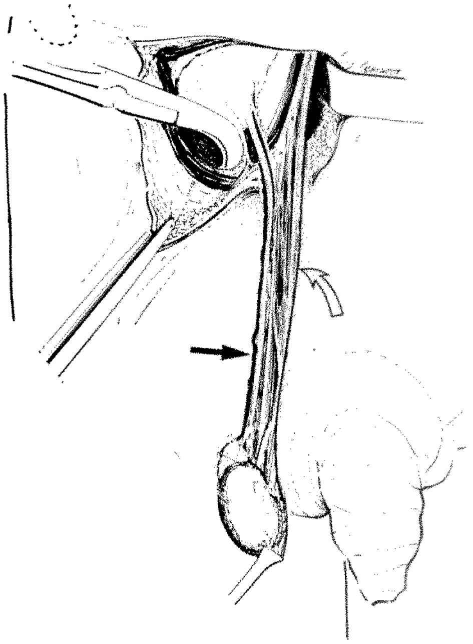

Fig. 5. Gentle traction on the testicle shows that sufficient retroperitoneal mobilization of the vessels and vas has been achieved. The Moynihan forceps has been passed into the empty deep inguinal ring.

testicle to be detached from the surrounding peritoneum and the gap so made in the peritoneum can be closed with a running suture of fine polypropylene. The testicle can then be drawn down and the testicular vessels and the vas freed in the manner already described. By this method we have found it possible to bring an abdominal testicle down into the scrotum at the one operation on six occasions.

7. The excellent exposure obtainable through this incision is also of great value in cases of anorchia. When the deep ring is examined from above and neither vessels nor vas are found to enter it, these two structures are sought in the retroperitoneal space. On two occasions we have found the vas at the pelvic

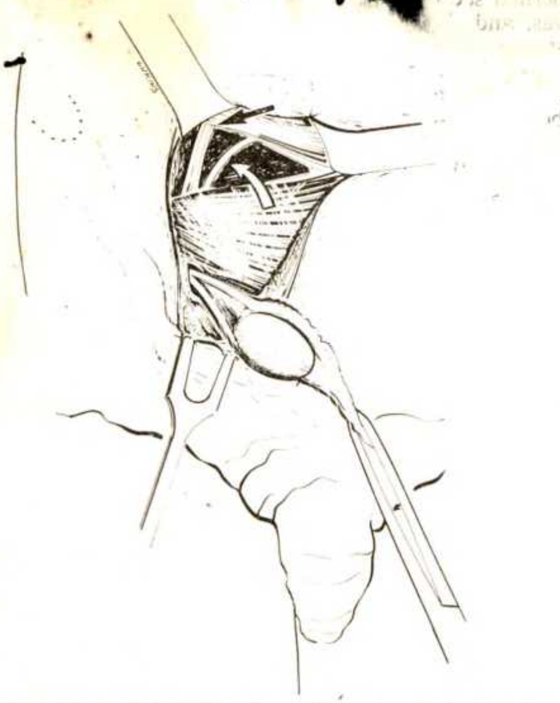

Fig. 6. The testicle has been drawn down through the deep ring and along the inguinal canal to emerge at the external abdominal ring. It is ready for placement in the scrotal pouch.

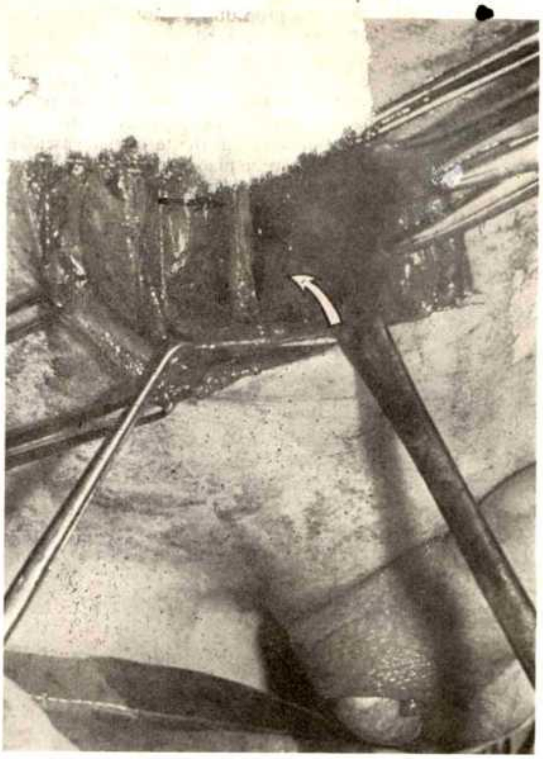

Fig. 7. An operative photograph which shows the typical appearance of the testicular vessels after placement of the testicle in the scrotal pouch. Although there has been no interference with the anatomy of the inguinal canal, the vessels take an almost straight line towards the testicle. This, view, which cannot be obtained during a Bevan orchidopexy, shows that there is no appreciable lateral deviation of the vessels as they pass through the internal ring. The emphasis which some writers (Gross, 1953; Whitaker, 1976) place on the need to incise the posterior wall of the inguinal canal in order to overcome this lateral deviation appears to be misplaced.

brim and traced it upwards to a point on the posterior aspect of the peritoneum at which it met the testicular vessels, but there was no sign of a testicle. Such a finding leaves no doubt that the testicle is absent.

8. Continuing the operation from paragraphs 5 or 6, the next step is to draw the testicle through the inguinal canal, and this is most easily done by lifting the lower skin flap and dissecting downwards with scissors in the subcutaneous plane to expose the superficial inguinal ring. A curved artery forceps is passed through the ring and up the inguinal canal to emerge at the deep ring. The tunica vaginalis is incised to expose the testis and the cut edge of the tunica is grasped by the artery forceps and used to draw the testicle down the inguinal canal and out through the external ring (*Fig.* 6).

9. When the extraperitoneal approach is used for a testicle near the superficial inguinal ring, we usually do not attempt to draw the testicle back into the abdomen as described in paragraph 5. The separation of the processus vaginalis, ligation of the neck of the processus and retroperitoneal dissection of the vessels and vas are completed as described above. Then the superficial inguinal ring is exposed by retraction of the lower skin flap and the testicle is expressed from the inguinal canal and gently held up. Freeing of all cremasteric and other fibrous bands holding the testicle proceeds as in a Bevan orchidopexy and when this is complete, the spermatic cord, which has already been freed within the abdomen, can be drawn out of the external ring. This combined exposure, from above and below the inguinal canal, allows an excellent view and very precise dissection.

10. A pouch is now formed in the scrotum as described by Petrivalsky (1931). The index finger breaks down the fibrous bands that obstruct the entrance to the scrotum and is passed to the lower pole of the scrotal sac. Holding the skin stretched over the index finger, a transverse incision about 1 cm long is made, through skin and dartos only, in the lower half of the scrotum. By using curved mosquito forceps as a dissector, a pocket is now formed between the skin and the deep fascia of the scrotum which will be large enough to hold the testicle comfortably. A 0·5-cm incision is made through the deep fascia on to the index finger and a curved mosquito forceps is passed into this incision, through the scrotum, to the region of the superficial ring. The forceps picks up an edge of the tunica and the testicle is then drawn down to the scrotum and gently pulled through the incision in the deep fascia which closes behind the testicle and prevents it retracting (*Fig.* 7). The testicle is now settled into the pouch and the skin closed over the top of it with interrupted mattress sutures of 3/0 catgut, which take a small bite of the tunica albuginea.

11. Finally, the incision is closed with sutures of 3/0 or 2/0 polypropylene according to the age of the boy. Interrupted sutures are placed in the transversus/internal oblique layer and then in external oblique: the knots are placed on the inner side of this aponeurosis.

Alternative technique

Fortunately, it is not necessary to decide on the use of the extraperitoneal approach before commencing an orchidopexy, although it is usually possible to do so. If the operation has been commenced in the usual way, through the inguinal canal, and the testicle proves unexpectedly difficult to mobilize, it is simple to change over to the extraperitoneal approach without making a new skin incision.

The upper skin edge is lifted and the skin and subcutaneous fat are dissected off the surface of external oblique until there is sufficient clearance to allow the muscle-splitting incision described in paragraph 2 to be used. This involves some firm [illegible] re is n[illegible]

[illegible] The [illegible]
commit surgeo[illegible]
We have made [illegible]
each time the extra length [illegible] ct[illegible]
bundle has allowed the testicle [illegible] d in a good position in the scrotum: later examination has shown that these testicles have remained in the scrotum and are of good size.

Results

The circumstances in which we first used the extraperitoneal approach have been previously described (Gatenby et al., 1975). These initial results encouraged us to continue to use this approach for all impalpable testicles. It has also been used for testicles that, lying within an inguinal hernial sac, can be massaged out of the inguinal canal and then be palpated over the superficial inguinal ring—what some call 'emergent' testicles.

Over a period of nearly 4 years, to September 1977, our unit has attempted orchidopexy in 196 patients of between 4 weeks and 16 years of age. Nineteen patients have had a bilateral operation, so a total of 215 explorations has been made.

On 123 occasions a palpable testicle (usually of superficial inguinal ectopic type) was mobilized by the Bevan technique and placed in a good position in the scrotum. Although in some cases these operations required wide dissection at and through the internal ring, on no occasion did we divide the inferior epigastric artery or open up the posterior wall of the inguinal canal. On follow-up all these testicles lay in a good position.

On 92 occasions the extraperitoneal approach was chosen. In one boy a Pfannenstiel incision was used to perform bilateral extraperitoneal orchidopexy and in another a La Roque transperitoneal incision was used, but neither of these approaches was found to be so convenient as the muscle-splitting incision, which was used for the other 89 explorations.

In 6 out of the 92 extraperitoneal operations orchidopexy was not possible. One testicle was found on the posterior abdominal wall 4 cm above the internal ring; it could not be adequately mobilized and it was removed (the contralateral testicle was normal). In 5 explorations no testicle was found, although the vas deferens was identified (Tibbs, 1961). In 2 cases the vas terminated in the abdomen at a point where it met the spermatic vessels. In the 3 other cases both vas and vessels were traced to the scrotum but no testicle was found. These seemed likely to have been cases of testicular atrophy following an undiagnosed neonatal torsion.

In the remaining 86 extraperitoneal operations a testicle was found and mobilized and in 85 the testicle was placed in a scrotal pouch. Of these 86 testicles, 6 were abdominal, 42 lay at the deep ring or in the inguinal canal and 38 were 'emergent'. An inguinal hernial sac was present in every case. Seven testicles had to be left in a rather high position but on later examination 5 were found to have taken up a normal position in the scrotum. Four of the 85 testicles successfully placed had been previously fixed over the pubic bone by a Bevan orchidopexy: when re-explored, the extraperitoneal approach was found to be advantageous because it allowed easy identification of the adherent point at which the neck of the sa[illegible] been ligated, and of the vessels and [illegible] th[illegible] helped subsequent dissection of these [illegible] the scar tissue in the inguinal canal. The [illegible] e not placed in the scrotum was an abdominal testicle that had to be left over the pubic bone for later re-exploration.

Seventy-six of the 86 extraperitoneal operations were performed more than 1 year before the time of writing and the results in 73 have been reviewed more than 1 year after operation. The testicle that had to be left outside the external ring remains there but the other 72 testicles all lie within the scrotum (although 4 of them lie in the upper half). Fifteen testicles were noted to be appreciably smaller than the opposite testicle at the time of operation and in 11 of these palpable growth has occurred. One of these 15 testicles was very small at operation and remains very small. The great majority of the other 57 testicles have kept pace with the growth of the opposite testicle, and none was thought to be smaller than at the time of operation.

There has been no instance of any weakness of the muscle-splitting incision and the healed scar is inconspicuous.

On four occasions appendicectomy was also indicated when a right extraperitoneal orchidopexy was being performed; the appendix was readily removed through the incision.

Discussion

Modern writers on orchidopexy (Whitaker, 1976; Williams, 1977) describe a procedure that does not differ in essentials from the operation illustrated and described by Bevan in 1903. Both Whitaker and Williams state that when there is difficulty a second higher incision can be used, but this incision is not further described. Others (Florence, 1957; Bourque, 1961) have already drawn attention to the advantages of an extraperitoneal approach, but they have used midline or Pfannenstiel incisions. The muscle-splitting incision gives equally good exposure through a smaller wound that heals strongly and causes very little pain. We now have no hesitation in using this approach whenever a testicle is impalpable or 'emergent'.

The results are most encouraging. There is no doubt in our minds that the extraperitoneal approach was instrumental in allowing many of the impalpable testicles to be placed in the scrotum in one stage. In the years before we began using this approach there was a fairly steady failure rate (i.e. we failed to place the testicle in the scrotum at the first operation) of 10 per cent for orchidopexy in our unit. Over the past 4 years in performing 210 orchidopexies the only 2 failures were an orchidectomy on an abdominal testicle and a case in which one testicle was left over the pubic bone.

The value of the approach was well seen in 6 infants under 2 years of age in whom it was necessary to operate on an inguinal hernia and when there was also incomplete testicular descent. The delicacy of the processus vaginalis at this age is well known, and it is easy to tear it near the deep ring, where repair of the rent can be very difficult. Both herniotomy and orchidopexy are made easier by the extraperitoneal approach, the neck of the sac being readily isolated when approached from above. Our youngest patient was 4 weeks old; the operation was straightforward and a year later the testicle is of good size and in a normal position in the scrotum.

The advantages of the approach can be summarized as follows:

1. The incision gives a good access, is comfortable postoperatively and heals strongly. A change can be made from the standard approach to the abdominal muscle-splitting incision during the operation without making a second skin incision.

2. The exposure of the retroperitoneal area which is obtained allows extensive mobilization of the testicular vessels and vas deferens. A wide search can be made for an abdominal testicle, and this allows a confident diagnosis of anorchia to be made if the search for the testicle proves negative. Neither of these aims can be consistently achieved through the Bevan exposure.

3. The ability to dissect out the hernial sac and separate it from the vessels above the inguinal ligament makes this part of the operation easier, especially in infants. This ability, and the easy mobilization of the vessels and the vas, removes the need to retract and enlarge the deep inguinal ring or to incise the posterior wall of the inguinal canal.

4. By the use of the Bevan or the extraperitoneal operation, 210 explorations revealed the presence of a testicle, 208 of which were placed in the scrotum. This is a great improvement on our former results. The position of the testicles has been seen to be maintained over one or more years and growth of the testicle is common.

So far we have not discovered any disadvantages that attend the use of the abdominal approach and it has now become an established procedure in this hospital.

or female genital
tract".

Br.Med.J. **i**, 318, 1976

NOW
FLAGYL
METRONIDAZOLE
INJECTION
FOR INTRAVENOUS INFUSION

proves decisive in anaerobic infections

Only with recent improvements in bacterial culturing techniques has the pathogenic role of anaerobes in post-surgical infections been fully recognized.[1-3] Now 'Flagyl' Injection offers you a decisive means of treating these infections – which are often life-threatening and often resistant to established antimicrobials. The response to 'Flagyl' Injection is rapid and dependable,[2] as it is consistently bactericidal to pathogenic anaerobes at tissue concentrations easily achieved in treatment. Bacterial resistance is not a problem,[2,4] and 'Flagyl' is highly acceptable – as eighteen years of use in other indications has established.

Dosage: Treatment: adults and children over 12 years: 100 ml by intravenous infusion eight-hourly, administered 5 ml per minute. Oral medication with 400 mg three times daily should be substituted as soon as this becomes feasible. Treatment for seven days should be satisfactory in most cases. Children under 12 years: as for adults but the single intravenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight and the oral dose on 7.5 mg per kg bodyweight. Prevention: adults and children over 12 years: 100 ml by intravenous infusion immediately before, during or after operation, followed by the same dose eight-hourly until oral medication (200 to 400 mg three times daily) can be given to complete a seven day course. Children under 12 years: as for adults but the single intravenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight and the oral dose on 3.7 to 7.5 mg per kg bodyweight. Precautions: pregnancy; lactation; clinical and biological surveillance if recommended duration of treatment exceeded; dosage may be halved for patients with renal failure; avoid alcohol; if 'Flagyl' is to be given to patients receiving oral anticoagulants the dosages of the latter should be recalibrated. Side effects and adverse reactions: occasionally an unpleasant taste, furred tongue, nausea, vomiting (very rarely), gastro-intestinal disturbance. Drowsiness, dizziness, headache, ataxia, skin rashes, pruritus, inco-ordination of movement, darkening of the urine very rarely. During intensive and/or prolonged therapy, peripheral neuropathy has been reported. A moderate leucopenia has been reported but the white cell count has always returned to normal before or after treatment has been completed. Transient epileptiform seizures in a few patients undergoing intensive, high-dosage metronidazole radiosensitization therapy.

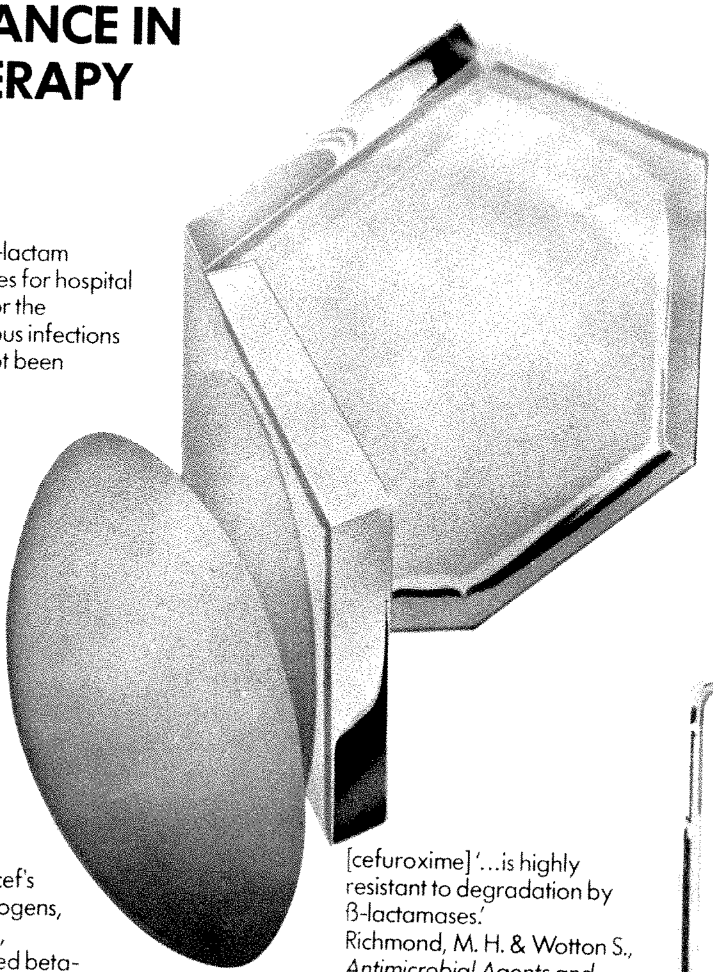
INJECTABLE

ZINACEF

cefuroxime sodium

A MAJOR ADVANCE IN ANTIBIOTIC THERAPY



Zinacef is a new, broad spectrum, beta-lactam antibiotic offering important advantages for hospital practice. It is particularly appropriate for the treatment of serious, or potentially serious infections where the causative organisms have not been identified or may be mixed.

Greatly enhanced stability to beta-lactamases

The value of commonly used beta-lactam antibiotics is being constantly eroded by the growth of resistant populations of bacteria.
Zinacef has a unique chemical structure with in-built protection against beta-lactamases which effectively places it in a new class of antibiotics.

A broader spectrum than most antibiotics

The ability to resist destruction results in a greatly extended clinical spectrum. Zinacef's bactericidal effect extends to many pathogens, both Gram-positive and Gram-negative, resistant or partially resistant to established beta-lactam antibiotics.

[cefuroxime] '...is highly resistant to degradation by β-lactamases.'
Richmond, M. H. & Wotton S., *Antimicrobial Agents and Chemotherapy* (1976) **10,** 219

With important therapeutic properties

- Zinacef has high bactericidal activity.
- Adequate serum levels are rapidly achieved and are well maintained.
- Zinacef is widely distributed with adequate levels in sputum, bile, bone and cerebrospinal fluid.
- Zinacef is not metabolised, but excreted, active and unchanged, in the urine.
- Zinacef has minimal toxicity, giving a wide margin of safety.
- Clinical trials have shown excellent renal tolerance.
- Zinacef can safely be used in neonates.
- Patient tolerance is excellent both intramuscularly and intravenously.
- Zinacef is compatible with commonly-used intravenous infusion fluids.
- There are no known clinically relevant adverse drug interactions.
- Zinacef can be used with other antibiotics to increase the antibacterial cover.

> '...this wide antibacterial cover should make it [Zinacef] a useful antibiotic for the treatment of infections requiring prompt parenteral therapy before the causative pathogen has been identified.'
> *British Medical Journal* (1978) **1**, 1279

ZINACEF

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 gram and infusion pack of 1·5 gram. All containing cefuroxime as cefuroxime sodium.

Indications
Serious bacterial infection, especially where the organisms have not yet been identified.
Conditions include:
Chest infections
Septicaemia
Soft tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Urinary tract infections
Ear, nose and throat infections
Meningitis
Gonorrhoea

Dosage
Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 gram t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary.
Infants and children: 30 to 100mg/kg/day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in two or three divided doses.
Gonorrhoea: Single dose of 1·5 gram (2 x 750mg i.m. into different sites).

Contra-indications
Hypersensitivity to cephalosporins.

Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria.
Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine.
As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage should be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.

Side effects
Adverse reactions are rare and generally mild and transient, e.g., rashes, gastro intestinal disturbance, candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).

Storage
The powder in the infusion pack and vials should be stored below 25°C and protected from light.

OUR THANKS TO ALL THOSE BRITISH SURGEONS WHO'VE HAD A HAND IN OUR SUCCESS.

For as long as British Surgeons have been wearing latex Surgeons' gloves, we have been making them.

While British medical research and discovery has been improving surgical procedures, ongoing research and improved rubber technology has developed a glove that precisely fits the needs of today's British Surgeon.

The continuing input of suggestions and comments by Surgeons plays a vital part in this evolution and this is why we'd like to thank you, the British Surgeon, for the hand you've had in our success.

The medical management of renal artery stenosis in transplant recipients

S. J. JACHUCK, R. WILKINSON, P. R. ULDALL, R. W. ELLIOTT, R. M. R. TAYLOR AND P. M. HACKING*

SUMMARY

The investigation, management and clinical course of 12 patients developing stenosis of the renal artery following transplantation are described. The possible aetiology of the three arteriographic patterns of stenosis is discussed. Surgical correction of graft arterial stenosis is difficult and may lead to graft loss, whereas the outcome with antihypertensive drug treatment with or without anticoagulants is good. Surgery should only be contemplated if medical treatment is failing or if renal function is deteriorating.

STENOSIS of the graft artery with hypertension is diagnosed in 3–16 per cent of renal transplant recipients (Doyle et al., 1975; Fine, 1975; Lindsey et al., 1975; Belzer and Salvatierra, 1976; Schacht, 1976). Although in some centres surgical repair is usually successful (Belzer and Salvatierra, 1976), most centres report a substantial failure rate, often with loss of the graft (Doyle et al., 1975; Fine, 1975; Schacht et al., 1976). This has led us to examine the results of medical treatment of renal artery stenosis in transplant recipients.

Patients and methods

Of 239 transplants performed in Newcastle between January 1972 and April 1976, renal artery stenosis with hypertension has been diagnosed in 12 (5 per cent). The clinical details of these patients before transplantation are given in *Table I* and following grafting in *Table II*. Transplant arteriography was performed because of severe hypertension. In 11 of the patients found to have renal artery stenosis a bruit was audible over the kidney or femoral artery. Renal arteriography was repeated after 1 year in those treated conservatively. Renal biopsy was performed in 4 and histological examination of the nephrectomy specimen in 3.

Angiographic findings and histology

Group 1: In 7 patients there was stenosis at the site of the anastomosis with normal intrarenal vessels (*Fig.* 1). Biopsy was performed in 3 of these patients and showed normal histology (*Table II*).

Group 2: Stenosis of the allograft artery beyond the anastomosis was seen in 2 patients with normal small vessels (*Fig.* 2). Renal biopsy was performed in one of these and the findings were normal.

Group 3: In the remaining 3 patients stenosis at the site of anastomosis was accompanied by irregularity of small vessels (*Fig.* 3). In the 2 patients biopsied there was fibrin deposition and fibroblastic proliferation in the arcuate and interlobular arteries, suggesting vascular rejection.

Management and outcome

Surgical: The renal artery was explored in 3 patients. In all cases it was enveloped in dense fibrous tissue. In 1 patient a saphenous vein bypass graft was performed, but the graft subsequently thrombosed and the kidney was lost. In the second case repair was considered impossible and nephrectomy was performed because at that time (1972) it was considered hazardous to attempt long term medical treatment. In the third case (H. W.) repair was not possible because of dense fibrosis. The kidney was left *in situ*; it continues to function at 1 year and control of hypertension is satisfactory.

K. P.	180	120	Malignant hypertension	Yes
S. O.	180	90	Glomerulonephritis	Yes

S, Systolic; D, diastolic.

Antihypertensive drugs alone: One patient died following a grand mal fit while being prepared for surgery, in 1 patient hypertension was controlled but nephrectomy was performed (*see above*), but 3 patients, all in group 1, continue with satisfactory blood pressure and good renal function more than a year after diagnosis of stenosis (*Table II*).

Antihypertensive drugs, warfarin and dipyridamol: In 5 patients (3 in group 1, 1 in group 2 and 1 in group 3) blood pressure control was difficult initially and warfarin and dipyridamole were added to the treatment regimen after inpatient control of severe hypertension. Thereafter control appeared easier and renal function did not deteriorate appreciably over the period of follow-up, except in patient S. O. in whom deterioration followed an episode of rejection 3 years after the diagnosis of arterial stenosis (*Table II*). There had been no progression of the arterial stenosis in the 4 patients re-examined after 1 year.

Antirejection treatment

The 2 patients in grou [illegible] ith histological evidence of rejection were treated with 3 [illegible] methylprednisolone over 3 days. In both patients the [illegible] vessels had reverted to normal on repeat angiogra [illegible] ut hypertension and the large vessel stenoses persisted, suggesting that the latter were responsible for the hypertension.

Discussion

Arteriographic patterns of the type we have encountered have been described by other groups (Smellie et al., 1969; Morris et al., 1971). Stenosis at the site of anastomosis (group 1) is usually attributed to trauma inflicted on the artery before or at the time of anastomosis (Smellie et al., 1969), although Belzer and Salvatierra (1976) have suggested that the use of silk suture material may be responsible. More distal stenosis (group 2) has been attributed to kinking of a

donor artery that is too long and also to the use of the end-to-side anastomosis (Morris et al., 1971). One of our patients with this type of stenosis (A. W.) had end-to-side anastomosis of renal to external iliac artery, but in the other (H. W.) the renal artery was anastomosed end to end to the internal iliac artery. Diffuse irregularity of intrarenal vessels is, as we have found, usually due to rejection (Morris et al., 1971). In 2 of our patients the donor was a child, but in only one of these cases was the stenosis at the anastomosis (E. Y.). In the other (A. W.) the stenosis appeared to be due to kinking and was apparently unrelated to the small calibre of the donor artery.

It is difficult to be certain that the hypertension was due to the demonstrated stenosis. Although one patient (H. W.) had been severely hypertensive before starting on dialysis, hypertension had not been a serious problem during dialysis and renin studies following transplantation revealed higher plasma renin activity in the left common iliac vein (the side of the transplant) than in the original renal veins. Five of the patients had been subjected to bilateral nephrectomy so that the diseased kidneys could not be incriminated. In 4 other patients hypertension had not been a problem during dialysis (*Table I*), making it unlikely that the diseased kidneys were the cause of the post-transplant hypertension. Two patients not subjected to bilateral nephrectomy (N. C. and B. W.) had been hypertensive on dialysis and it is difficult to be certain that the undoubted stenosis of the transplant artery was the cause of their post-transplant hypertension.

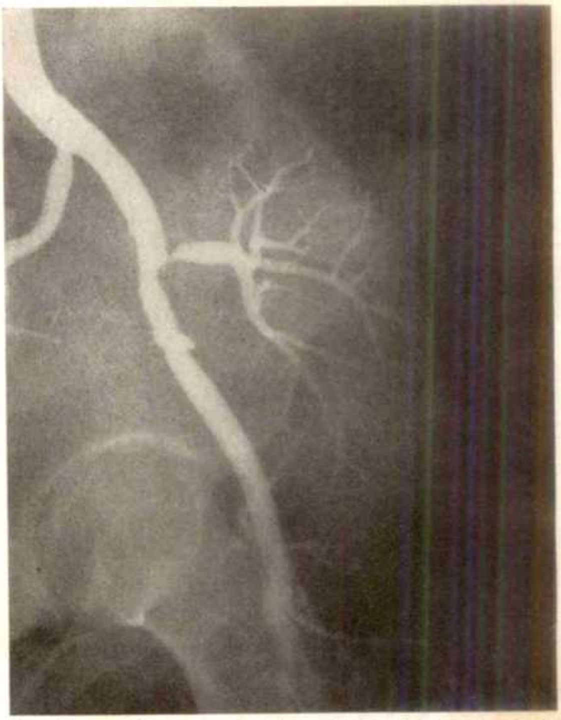

Fig. 3. Group 3 comprised patients with stenosis at the site of anastomosis accompanied by irregularity of small vessels.

In the 9 patients followed up for 1 year or more hypertension p[illegible] despite reduction of the dose of prednisone t[illegible] than 10 mg/day, suggesting that high steroid dosage was not the cause of hypertension. Renal function was good in 11 of the patients so that hypertension was not likely to be due to chronic vascular rejection.

It seems likely, therefore, that, in the absence of other detectable causes, the demonstrated renal artery stenosis was responsible for post-transplant hypertension in the majority of the 12 patients described. It is, of course, impossible to be certain of this except by observing the response to surgery.

Because of the coexistence of anastomotic stenosis and kidney rejection in two patients (E. Y. and S. O.), we thought it possible that transplant artery stenosis might be due, in some cases, to a local rejection phenomenon with adherence of platelets and deposition of fibrin. This provided the rationale for the addition of warfarin and dipyridamol to antihypertensive therapy. Even if this were not the mechanism it was thought that this treatment might delay the progression of stenosis. Whilst these patients did well, so also did 3 of the 5 patients treated with antihypertensive drugs alone (one other patient died and one was subjected to nephrectomy in this group). We are not able, therefore, to comment further on the role of these drugs in the treatment of transplant artery stenosis. However, a controlled trial of their use may be justified on the basis of our experience. A multicentre trial with all its difficulties would be necessary in view of the rarity of this complication of transplantation. Anticoagulants can, of course, only be given after blood pressure control has been achieved, if necessary with parenteral therapy.

Because of the rather poor results with surgical treatment of transplant artery stenosis (Doyle et al., 1975; Fine, 1975; Schacht et al., 1976) and the difficulty in determining the functional significance of any anatomical stenosis demonstrated (Gupta et al., 1976), most transplant surgeons consider surgery only if hypertension is accompanied by deteriorating renal function, as in one of our patients (M. V.), or if hypertension cannot be controlled medically. Our experience supports this approach and we have not lost a patient, nor indeed a kidney, from renal artery stenosis since the death of patient A. W., which occurred in 1972. Even patient M. V., who had slightly impaired renal function initially, has suffered no further reduction in function.

Transplant arteriography is worth while in patients with severe hypertension even if surgery is not contemplated, since (*a*) a positive diagnosis of arterial stenosis may spare the patient bilateral nephrectomy, (*b*) the initial arteriogram will give an indication of the feasibility of surgery should medical treatment fail, and (*c*) small vessel changes may be revealed that indicate the likelihood of vascular rejection and the need for antirejection treatment if this is confirmed by biopsy.

Acknowledgements

We would like to thank Professor D. N. S. Kerr for permission to include his patients in the study. We are very grateful to Mrs R. Grieveson for her valuable help in collection of data and for secretarial assistance. We are grateful to Dr A. R. Morley for performing the histological examinations.

Arteriovenous grafts for vascula in haemodialysis

R. C. KESTER*

SUMMARY

The outcome of 68 arteriovenous grafts placed in 46 patients requiring haemodialysis was studied over a period of 3·5 years. The biological grafts included autogenous saphenous vein, modified bovine carotid artery and human umbilical cord vein allograft, whereas the synthetic grafts comprised Sparks Dacron mandril, expanded reinforced polytetrafluoroethylene and knitted Dacron velour. These subcutaneous grafts were arranged as looped or straight configurations in the forearm or thigh. Of 59 grafts evaluated in patients with end-stage renal failure, only 48 per cent of the forearm grafts performed well, compared with 85 per cent of the thigh grafts. Although only 38 per cent of the looped grafts were successful, 78 per cent of the straight grafts functioned satisfactorily. Synthetic grafts suffered less serious complications than the commercial biological grafts.

MAINTAINING easy access to the bloodstream is both the keystone and Achilles heel of long term haemodialysis in end-stage renal failure. The most popular means of vascular access for close on two decades have been the external arteriovenous or Scribner shunt (Quinton et al., 1960) and the internal arteriovenous or Cimino–Brescia fistula (Brescia et al., 1966). Unfortunately, these primary procedures to obtain access to the circulation may fail sooner or later because of thrombosis, infection or inadequacy of the blood vessels. When all the forearm and ankle vessels have been obliterated by repeated primary procedures, then continued intermittent haemodialysis has been made feasible through the development of second-stage procedures, which include the implantation of subcutaneous arteriovenous grafts. This paper records the results obtained in one centre using a variety of grafts for continued haemodialysis in problem patients.

Table I: INDICATIONS FOR AN ARTERIOVENOUS GRAFT

Cimino–Brescia fistula impossible when forearm vessels:
  (*a*) obliterated by previous infusions, shunts or fistulas
  (*b*) indiscernible because of obesity or cachexia
  (*c*) unsuitable because of small calibre
Inadequate development of veins by arteriovenous fistulas
Scribner shunt not feasible when ultimate fistula fails
Imminent kidney transplant unlikely when ultimate fistula or shunt fails.

Total	68	

Patients and methods

During the period of study, extending from June 1974 to December 1977, 68 arteriovenous grafts were implanted subcutaneously in 46 patients. The group comprised 19 men and 27 women, aged between 15 and 64 years, with an average age of 41. Apart from 5 cases with disseminated cancer of bronchus or bladder, all patients had end-stage renal failure. The 5 exceptions were scheduled for magnesium depletion in an attempt to control their spreading cancer. The indications for establishing a subcutaneous arteriovenous graft are listed in *Table I*. The number of previous first-stage vascular access procedures undertaken in each patient varied between none and 9, with a mean of 3·7.

The types and number of vascular grafts used in the study are listed in *Table II*. All grafts had an internal diameter of about 6 mm. The synthetic prostheses used were the Sparks Dacron mandril (American Hospital Supply UK Ltd) (*Fig*. 1), expanded microporous reinforced polytetrafluoroethylene (PTFE) or Gore-Tex (W. L. Gore UK Ltd) (*Fig*. 2) and knitted Dacron velour or Vasculour-D (USCI International Ltd) (*Fig*. 3). The biological grafts used were reversed autogenous saphenous vein, dialdehyde-treated human umbilical cord vein allograft or HUCVAG (Gene-Tec Scientific Ltd) (*Fig*. 4), ficin-digested bovine carotid artery graft or Surgikos Artegraft (Johnson and Johnson Ltd) (*Fig*. 5), gluteraldehyde-treated and antibiotic-treated bovine carotid artery grafts (Yorkshire Regional Tissue Bank) (*Figs*. 6, 7). In preparation of the two last-mentioned grafts, fresh bovine carotid arteries collected from the local abbatoir were treated in alternative ways: the first group was immersed in 0·5 per cent phosphate-buffered gluteraldehyde solution for 48 h and then stored in the solution. The second group was immersed in Medium 199 (Gibco Bio-cult Ltd) in which was dissolved gentamicin 4 mg/ml, methicillin 10 mg/ml, erythromycin 6 mg/ml, mycostatin 2500 units/ml and fetal calf serum to a concentration of 10 per cent. The arteries were stored in the solution at 4 °C for no longer than 5–6 weeks.

If the vessels of either forearm were judged to be inadequate, then the graft was placed in the thigh. In the forearm and thigh, the graft was usually arranged as a straight configuration, but when poor distal forearm vessels did not permit a straight configuration, then a loop based on the cubital fossa was fashioned. It was decided to place all the commercial bioprostheses in the thigh.

For a forearm loop, the brachial artery was bridged to the widest vein in the cubital fossa, the loop extending to the distal forearm. For a straight forearm configuration an appropriate vessel in the distal third of the forearm was connected to an antecubital vessel. In the thigh the common femoral artery was usually connected to the superficial femoral vein in the distal part of Hunter's canal. During the early phase of the study, a few thigh loops based on the femoral vessels were established, the loops extending to mid-thigh level.

The vascular suture used was 5/0 or 6/0 Prolene (Ethicon Ltd). Usually an interval of 10–14 days was allowed before a graft was cannulated for haemodialysis, so that the surgical wounds could heal. Many of the patients underwent haemodialysis at their homes.

Results

Patency and function (*Table III*)

Primary failure of a graft was defined as the inability of the prosthesis to support even a single dialysis session because of thrombosis, inadequacy or sepsis.

Autogenous saphenous vein grafts: Two looped and 2 straight grafts thrombosed during the first postoperative week. A solitary thigh loop and a forearm loop were patent for 3 and 13 months respectively, and supported an average of 90 dialysis sessions. The 4 straight grafts in the forearm did worse, remaining patent for about 3 months, supporting about 62 dialysis sessions.

HUCVAG: Two grafts thrombosed at 1 and 2·5 months respectively, and were found to be too degenerative to salvage. Persistent sepsis of one graft prevented its use for haemodialysis, and it was excised after 5 months because of secondary haemorrhage. Two further grafts became aneurysmal after 8 and 11 months respectively and were excised. One graft remains trouble-free at 12·5 months, supporting about 102 dialysis sessions.

Bovine carotid artery grafts (*ficin-digested grafts, Surgikos Artegraft*: The 4 grafts achieved a mean patency of 12·3 months, supporting about 129 dialysis sessions. One patient died of exsanguinating haemorrhage from a cannulation site after 11 months and a second graft had been patent for 5·5 months at the time of the patient's death. The third graft became aneurysmal and then thrombosed by 11 months. The fourth graft remained patent for 16·5 months and then had to be excised because of uncontrollable bleeding from cannulation sites.

Gluteraldehyde-treated grafts: Two straight grafts in the forearm thrombosed at 9 weeks and 5 months respectively. Two thigh grafts remain open after 8·5 months of function.

Antibiotic-treated grafts: Two patients in the group died in the early postoperative period. A forearm looped graft and 2 thigh grafts remain open after a minimum of 5 months, and have each supported about 60 dialysis sessions.

Sparks Dacron mandril: Five of the 11 grafts thrombosed at an early stage and never functioned. None of the arm or thigh loop grafts remained patent beyond 2 months. Two of the 3 thigh straight grafts remain trouble-free and open after 23 months.

Expanded PTFE grafts (*Gore-Tex*): Two of the 8 forearm straight grafts remain patent and functional at 8 and 9 months respectively. Three primary failures occurred within 14 days of operation because of poor arterial inflow. The 5 functioning grafts supported an average of 78 dialysis sessions. Four of the 5 forearm looped grafts functioned for an average of 3 months, but only 1 remains patent. On the other hand, the 9 thigh straight grafts functioned best of all, with a duration of patency varying from 4·5 to 17 months (mean patency of 10 months). Four grafts remain open, while 2 were removed because of infected cannulation sites and a further graft was excised because of brisk bleeding from cannulation sites. The occlusion of one graft at 4·5 months was most probably related to the extensive atheromatous disease of the femoral artery. The ninth graft was patent for 6·5 months at the time of the patient's death.

Knitted Dacron velour grafts (*Vasculour-D*): All 6 grafts implanted in the thigh in straight configuration have given trouble-free service. They remain patent after nearly 4 months and they have supported some 30 dialysis sessions. One forearm loop graft suffered primary failure due to inadequate arm vessels.

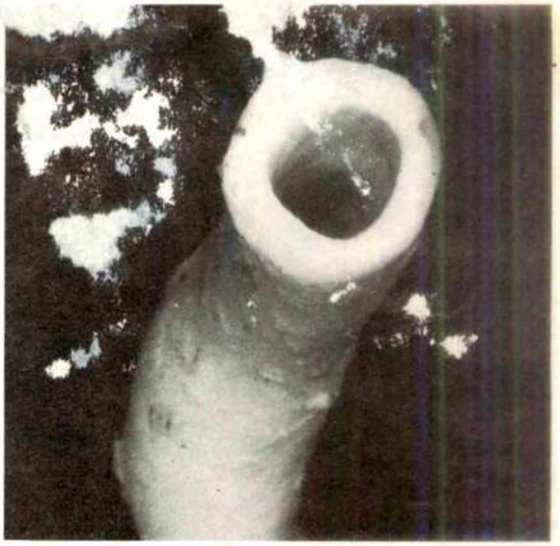

Fig. 7. Antibiotic-treated bovine carotid artery graft, 6 mm internal diameter.

Assessment of graft function: The success of each arteriovenous graft was assessed by the arbitrary criterion of whether the graft supported a minimum of 24 dialysis sessions. The grafts implanted in the 5 cancer patients and in those patients who died during the first 2 postoperative months were not included, leaving 59 grafts to be evaluated (*Table IV*). Whereas only 48 per cent of forearm grafts were successful, 85 per cent of thigh grafts performed well. Straight grafts enjoyed a measure of success of 78 per cent, compared with 38 per cent of looped grafts.

Complications (Table V)

Graft thrombosis: Thrombectomy was unsuccessful in the three clotted HUCVAGs because the grafts were too degenerative. Thrombectomy was successful in one bovine Artegraft, but not in a thrombosed gluteraldehyde-treated graft placed in the forearm. Only 3 of 6 attempts at thrombectomy performed in 5 of the Sparks mandril loop grafts succeeded.

None of 6 thrombectomies in 4 forearm Gore-Tex grafts achieved patency, but 9 such attempts with 5 thigh grafts established continued patency in all but one graft.

Deep vein thrombosis: One patient with a thigh Gore-Tex graft and another with a thigh Sparks mandril graft developed ipsilateral iliofemoral venous thrombosis.

Venous outflow problems: Five thigh grafts required reduction of their blood flow by partial ligation because of (*a*) gross unremitting oedema of the [illegible]eg (1 Gore-Tex and 2 bovine Art[illegible]afts); (*b*) venous pressure interfering [illegible] dialysis [illegible] HUVCAG); (*c*) increased ve[illegible] return produ[illegible] cardiac failure (1 bovine Arte[illegible]).

Arterial embolism: One pati[illegible] femorofemoral arterial 'jump' graft of Go[illegible] ped painful red areas on the sole of th[illegible] because of severe

Table III: CONFIGURATIONS AND OU[illegible] [illegible]TERIOVENOUS GRAFTS FOR HAEMODIALYSIS

Graft	No.	Configuration	Primary failure	Range of patency (mth)	Mean patency (mth)	Mean no. dialysis sessions

Bleeding	0	1	2	0	0	1	1	0
Haematoma	0	0	0	0	0	1	0	0
Sepsis	0	1	0	0	0	1	4	0
Aneurysm	0	2	1	0	0	0	0	0

bleeding from cannulation sites, excision of the graft was required.

Arterial 'steal': One patient with a HUCVAG, with obliterated ankle vessels, subsequently experienced severe ischaemia of the foot, presumably brought on by an arterial 'steal' phenomenon. A below-knee amputation was performed.

Bleeding: Secondary haemorrhage from a graft is a very serious problem, because 4 thigh grafts complicated in this manner (HUCVAG, bovine Artegraft, Sparks mandril and Gore-Tex) had to be excised. One further patient with a bovine Artegraft suffered a fatal exsanguinating haemorrhage.

Sepsis: Sepsis along the track of the graft was ineradicable, and 1 thigh Sparks mandril graft and 2 thigh Gore-Tex grafts had to be excised.

Aneurysm formation: Four bioprostheses (3 HUCVAG and 1 bovine Artegraft) developed multiple aneurysms and the grafts were removed thereafter.

Discussion

In end-stage renal failure, when repeated first-stage procedures such as the Scribner shunt or Cimino–Brescia fistula have failed to accomplish vascular access and early kidney transplantation is unfeasible, then second-stage procedures are employed to permit continued dialysis. These may include interposed grafts between suitable artery and vein; translocation of the superficial femoral artery to a subcutaneous position (Brittinger et al., 1970); brachial or proximal radial artery–cephalic vein fistula (Cascardo et al., 1970); and femoral vein and artery catheterization by the Seldinger technique (Shaldon et al., 1961). Larger arteriovenous shunts are now available, such as the Thomas shunt or large vessel appliqué (Thomas, 1970) and the Allen–Brown shunt (Extracorporeal Medical Specialties Incorporated).

With the rapid development of new biological and synthetic graft materials for vascular replacement, not surprisingly, the implantation of a subcutaneous arteriovenous graft has proved to be a popular method of achieving vascular access. Considering first the biological grafts, haemodialysis through autogenous saphenous vein loops in the forearm was first introduced by May and colleagues in 1969. A failure rate of 20–25 per cent in the first 3 months of implantation has been observed, while only 50 per cent of grafts remain patent by 1 year (Foran et al., 1975). Although individual grafts may function for nearly 4 years (Zerbino et al., 1974), many wide-bore vein grafts eventually fail due to intimal fibrosis and aneurysmal dilatation (Foran et al., 1975).

Although the bovine carotid artery graft was originally developed for arterial bypass surgery (Rosenberg et al., 1966), Chinitz and co-workers (1972) were the first to use the xenograft as an arteriovenous conduit to facilitate haemodialysis. The graft is prepared by digesting the adventitia and elastica proteins with ficin, a protease found in fig juice. The remaining collagenous structure is not only strengthened by tanning with dialdehyde starch, but is also rendered essentially non-antigenic. A 1-year patency rate of about 70 per cent is reported (Foran et al., 1975; Rolley et al., 1976), but there is a striking prevalence of needle site infection, bleeding episodes, aneurysms and poor salvageability. Because of a low patency rate of 42 per cent, a sepsis rate of 7 per cent and an aneurysm incidence of 5 per cent, Dale and Lewis (1976) have abandoned using the xenograft for arterial reconstruction. The mean patency rate of some 12 months for the grafts in the present study is in keeping with the other series, but serious complications such as aneurysm formation, massive bleeding and venous outflow problems have made further use of the Artegraft impracticable in this centre.

There has been a sustained interest in the preservation of vascular tissue using two main methods: gluteraldehyde treatment and antibiotic treatment. For instance, the Hancock 'stabilized gluteraldehyde-process-treated' porcine aortic valve (Bowman et al., 1973) has been implanted in many patients with successful function for up to 6 years (Dexter, 1977), and such valves are now available commercially (Edwards Labs). Several investigators have evaluated fresh homograft aortic valves treated with antibiotic cocktails, and these valves have also enjoyed a favourable outcome (Angell et al., 1973). Preservation of bovine carotid arteries collected from the local slaughterhouse is based on the long term studies of Dexter at the Yorkshire Regional Tissue Bank, Wakefield. Despite its shorter shelf-life, the antibiotic-treated graft is preferred to the gluteraldehyde-treated artery because it is more compliant, softer and easier to handle.

Preparation of the HUCVAG is broadly similar to that of the Surgikos Artegraft, whereby, following dilatation of the central umbilical vein, the Wharton's jelly component of the cord is strengthened by tanning either with dialdehyde starch (Mindich et al., 1977) or with gluteraldehyde (Dardik et al., 1976). [illegible] by the two latter groups of the outcome of these homografts are not persuasive, as they give an early thrombosis rate of 40–74 per cent, accompanied by a salvage rate of only 50 per cent. These two factors, in addition to the high cost of the graft and the risk of aneurysm formation, have led to suspension of further implantation in this centre.

In meeting the challenge to provide vascular access in a problem patient, synthetic grafts provide creditable alternatives to the biological grafts. One example, the Sparks mandril, consisting of two layers of knitted Dacron tubing surrounding a flexible inner rod, is buried subcutaneously (Sparks, 1972). When the inner rod is withdrawn after a minimum period of 6 weeks, ingrowth of fibrous tissue has converted the mandril into a vascular prosthesis. Although initially the concept appeared attractive, interest in the mandril has now waned, because of the long maturation period and the incidence of graft closure and aneurysm (Hallin and Sweetman, 1976). The present study confirms their finding that successful long term function can be achieved, provided that the Sparks mandril is anastomosed to wide-calibre vessels.

Early evaluation of expanded reinforced microporous PTFE (Gore-Tex) has shown a patency rate of 86 per cent for over 400 grafts implanted for haemodialysis (Gore Associates Inc., 1977). In the present study, only one thigh graft remained irretrievably closed, probably because of an atheromatous femoral artery. Arteriovenous fistulas and grafts are prone to thrombose if hypotension is incurred after a dialysis session. Thrombectomy is most easily carried out in a Gore-Tex graft, and it is followed by long term patency, provided the inflow and outflow of blood is adequate. Because these requisites were deficient in the arm grafts, salvage attempts here were of little avail.

Dacron velour (Vasculour-D) grafts are warp-knitted from texturized yarn to give loops perpendicular to the flow surface, similar to velvet, producing a fabric of intermediate porosity. These characteristics promote fibrous tissue ingrowth, a well-formed neo-intima and excellent rates of patency in arteriovenous grafts (Flores et al., 1973; Lindenauer et al., 1974). Regarding the three types of synthetic graft, although the Sparks mandril is by far the cheaper, Gore-Tex and Vasculour-D do not require a prolonged maturation period after implantation and also both have received more favourable reports.

In conclusion, conspicuous factors emerge following consideration of the outcome of these 68 arteriovenous grafts for haemodialysis. The first outstanding fact is that a graft placed in straight configuration has a better outcome than a looped graft. The second feature is that a graft located in the thigh enjoys greater success than one in the arm. In general, the patients preferred the thigh location because both hands were then freed for cannulation manoeuvres. Finally, the synthetic grafts incurred less serious complications than the commercial bioprostheses currently available.

Acknowledgements

I am deeply thankful to Mr Frank Dexter, Director of the Yorkshire Regional Tissue Bank, Pinderfields Hospital, Wakefield, for advice and for the supply of bovine carotid grafts. I am very grateful to Mrs Alice Halliwell for typing the manuscript.

Neurofibrosarcoma of the duodenum in von Recklinghausen's disease

W. O. THOMSON, R. CARACHI, C. B. WOOD AND D. W. SHORT*

SUMMARY

The clinical features and surgical management of 2 patients with neurofibrosarcoma of the duodenum in association with von Recklinghausen's disease are described. The tumours were excised and the resulting duodenal defects closed satisfactorily using the jejunal serosal patch technique. Three such neurofibrosarcomas reported previously in English are reviewed.

NEUROFIBROMA and neurofibrosarcoma of the small bowel account for 2·4 per cent and 0·6 per cent respectively of small bowel tumours (Sivak et al., 1975). Over 80 per cent of enteric neurofibromas occur without cutaneous neurofibromatosis (River et al., 1956), but 11 per cent of patients with von Recklinghausen's disease develop such tumours (Das Gupta, 1969). The incidence of sarcomatous degeneration of neurofibromas in patients with von Recklinghausen's disease rises with age and length of follow-up. It has been reported to range from 4·4 per cent (Knight et al., 1973) to 66 per cent (Das Gupta, 1969). Malignant change in small bowel neurofibromas has rarely been reported. We were able to find details of only 14 cases reported previously: 6 neurofibrosarcomas were in the duodenum and of these, 3 were in patients with von Recklinghausen's disease. We present 2 further cases with emphasis on the clinical presentation and surgical management.

Case reports

Case 1: A 64-year-old woman with von Recklinghausen's disease and a 24-h history of severe right-sided upper abdominal pain and two episodes of haematemesis was admitted as a surgical emergency. On examination, she had generalized peritonitis and a diffuse mass was palpable in the right upper quadrant. At laparotomy, the antimesenteric border of the entire small bowel was studded with many small neurofibromas. On the anterior wall of the second part of the duodenum was a large necrotic tumour which had perforated the duodenum and also invaded the hepatic flexure of the colon. The duodenal tumour was excised and a right hemicolectomy performed. The defect in the anterior duodenal wall, which was 4×3 cm in diameter, was repaired using a loop of proximal jejunum, brought through the mesocolon and sutured to the free edge of the duodenal defect as a serosal patch. The operation was completed with a proximal jejunojejunostomy to divert intestinal contents from the region of the duodenal repair.

The patient's condition remained poor. On the fifth post-operative day she developed bilateral ileofemoral thrombosis and pulmonary embolism and died 5 days later. Post-mortem examination showed that death was due to bronchopneumonia and multiple pulmonary emboli. Histology of the tumour (*Fig.* 1) showed it to be a neurofibrosarcoma infiltrating the hepatic flexure of the colon.

Case 2: A 34-year-old male Pakistani with von Recklinghausen's disease was admitted as an emergency with a 48-h history of central and right-sided abdominal pain and bilious vomiting. On examination, his abdomen was tense, with rebound tenderness over a diffuse mass to the right of the umbilicus. Bowel sounds were normal. At laparotomy a large lobulated tumour arising from the anterior aspect of the second part of the duodenum projected through the mesocolon. There were also multiple neurofibromas studded along the antimesenteric border of the jejunum. The tumour was mobilized and resected leaving a defect of 5×3 cm in the anterior duodenal wall. This was repaired, as in the first case, by a jejunal serosal patch. As the tumour had infiltrated the mesocolon and compromised the circulation to the ascending colon, a hemicolectomy was also performed. The patient remains well 2 years later.

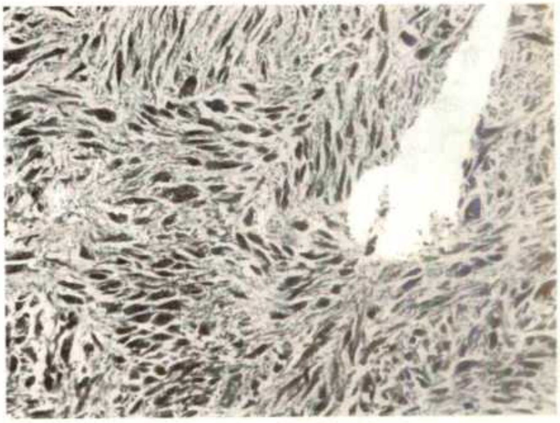

Fig. 1. *Case* 1. Photomicrograph of duodenal neurofibrosarcoma. (HE. × 225.)

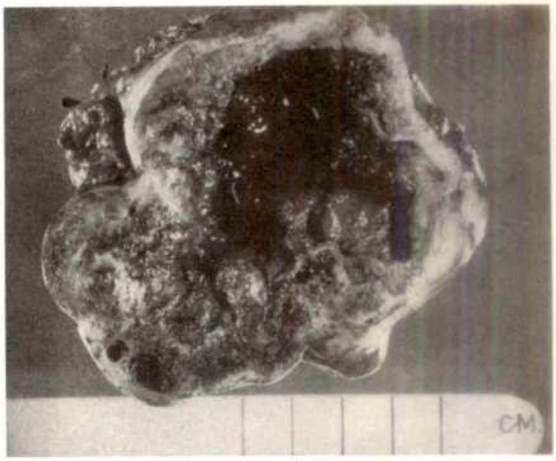

Fig. 2. *Case* 2. Duodenal neurofibrosarcoma, showing necrotic haemorrhagic central cavity.

The resected tumour was 8 cm in diameter with central necrosis and recent haemorrhage (*Fig.* 2). Histologically it was a neurofibrosarcoma which had penetrated the duodenal wall.

Discussion

Most intestinal neurofibromas are asymptomatic and are incidental findings at laparotomy or at post-mortem (Nilsson and Jonsson, 1957). They can, however, cause abdominal discomfort, melaena or obscure anaemia (River et al., 1956) and the diagnosis

LIBRARY

of intestinal neurofibromatosis should be considered whenever a patient with von Recklinghausen's disease develops such symptoms. In cases reported in the literature there is an average delay of about 3 years before the diagnosis is made (Sivak et al., 1975). A high index of suspicion, thorough radiological and endoscopic investigation and willingness to perform early laparotomy may prevent life-threatening complications such as malignant degeneration or massive gastrointestinal bleeding.

Neurofibrosarcomas probably arise from malignant degeneration of pre-existing neurofibromas in the autonomic plexuses of the bowel wall. These tumours are very vascular, and, as they grow, the centre tends to become haemorrhagic and necrotic. Bleeding into the centre of the tumour probably caused the pain with which our second patient presented. Continued tumour growth may result in mucosal infiltration, with ulceration and haemorrhage into the gut. As a result of mucosal erosion the necrotic central part of the tumour may be exposed to the intestinal contents, and become infected (Cedermark, 1949). The tumour may also ulcerate through the peritoneal surface of the duodenum causing perforation and peritonitis, as in our first patient.

Three cases of duodenal neurofibrosarcoma in association with von Recklinghausen's disease have been previously reported (Russell, 1965; Beaven and Donovon, 1970; Clapp and Haas, 1971). All three patients had past histories of abdominal pain, melaena or anaemia, which had been investigated without a definite diagnosis being made. Each of these patients subsequently presented as a surgical emergency. Two of the patients had developed intra-abdominal sepsis owing to erosion of the tumour through the duodenal wall, and both died soon after operation. The third patient presented with massive intestinal haemorrhage. This patient survived resection of the tumour but a long term follow-up was not reported.

Three patients with duodenal neurofibrosarcomas in the absence of cutaneous neurofibromatosis have been reported previously (Cedermark, 1949; Elliot and Hansson, 1951; Nilsson and Jonsson, 1957). In two of these patients the presenting symptoms were dyspepsia and melaena and a radiological diagnosis of duodenal tumour was made on barium meal examination. In the third patient, results of barium meal examination were normal and the diagnosis was made at laparotomy. In 2 cases the tumours were not resectable and the patients died with metastases 3 years and 18 months respectively after operation. In the third patient a small tumour was excised but no long term follow-up was reported.

Resection of duodenal lesions is complicated by the difficulty of closing the resulting defect. The serosal patch technique is a relatively simple procedure and has been used successfully to close duodenal fistulas after gastroduodenal surgery (Jones et al., 1973) and allows resection of colonic tumours involving the duodenum (Ellis et al., 1972). We believe that with the use of the jejunal serosal patch to close the duodenal defect, large tumours of the second part of the duodenum can be successfully resected even under emergency conditions.

Pyeloduodenal fistula: a case report and review of the literature

A. J. G. BATCH, A. H. AMERY AND E. R. DY*

SUMMARY

A case of the rare condition of pyeloduodenal fistul presented—the thirty-second case so far recorded in literature. The authors consider that this instance s some of the features typical of the cases so far rep ed.

The literature is reviewed and the aetiology, presentation, diagnostic methods and treatment are briefly discussed.

FISTULOUS connection between the renal and alimentary tracts is itself unusual and spontaneous pyeloduodenal fistula is one of the rarer types. In exhaustive review Abeshouse (1949) found or cases of pyeloduodenal fistula in a total of 277 alimentary fistulas of all types. W 31 reported cases (*Table I*) and case, due to chronic pyonephro

Case report

A 44-year-old man with fever, general mala anorexia. After 10 right loin pain, dysuria, urinary symptoms settled after a fever and malaise continued. Ten da ed to hospital for investigation.

Further questioning revealed a 4-year history of recurrent febrile illnesses, each similar to his current attack, but there was no past history of urinary disorder.

On admission he had a fever of 39 °C and a tender mass in the right loin. Investigations showed a haemoglobin of 11·4 g/dl and a WBC of 17·3 × 10⁹/l. Biochemistry was normal, MSU contained red cells but no growth and an intravenous pyelogram showed a normal left renal tract but a non-functioning right kidney.

Four days after admission the patient's temperature suddenly fell to normal with a dramatic improvement in his general condition unassociated with any new symptoms. Cystoscopy the same day revealed no abnormality. A retrograde pyelogram of the right side revealed a grossly distorted pelvicalyceal system and free flow of contrast medium into the duodenum (*Fig.* 1).

Renal puncture was then performed under X-ray control: 80 ml of pus were aspirated and contrast studies confirmed the changes in the right kidney (*Fig.* 2). Culture of the pus yielded a heavy growth of *Escherichia coli* and the patient was started on a course of cephradine. He was discharged home feeling well on the seventh day.

Two weeks later a further intravenous pyelogram showed a thin shell of renal tissue with large cystic spaces on the right but no clear outline of the pelvicalyceal system or ureter. Contrast medium was seen in the small bowel on later films.

Although symptom-free the patient was readmitted 4 weeks after discharge from hospital for exploration of the right kidney. The kidney was approached posteriorly and dense fibrosis was encountered around it, especially at the hilum, where a fistulous connection was found between the dilated renal pelvis and the posterior aspect of the duodenum (*Fig.* 3). Nephrectomy was performed, dividing the fistula and repairing the duodenal defect. The patient's postoperative recovery was uneventful and he was discharged home on the tenth day.

Macroscopically, the specimen revealed a grossly dilated pelvicalyceal system lined with blood clot and exudate surrounded by a thin shell of kidney tissue. The microscopic appearances were those of chronic pyonephrosis.

iscussion

Cases of pyeloduodenal fistula have been divided into traumatic and spontaneous, no case of congenital fistula ever having been reported. With one exception, all the reported cases involved the right kidney. Arendt and Brockman (1934) reported a case involving the left kidney and the terminal duodenum.

Traumatic fistulas form the smalle group, but since 1945 these appear to be incr asin n requency (Bissada et a . 19). Reporte ha been due to b llet wo Dougal a ky, 972; Bissada penetrati denum by ingested dies (Abe 49; Schimmel, 1971), injuries (I o; Arthur and Morris,), surgica on of the renal tract eshou al., 1961) and drainage of suppo ts (the hydronephrotic renal num (Morson and Stiddolph, l., 1973). Trauma may lead to ood or urine into the perinephric nric abscess and eventual rupture into um (Abeshouse, 1949). This process is spontaneous fistula formation in the nce of chronic renal inflammatory disease. Probably some cases of spontaneous fistula are preceded by an episode of trauma, the diseased renal pelvis being more likely to rupture.

Generally, spontaneous pyeloduodenal fistula results from a pathological process in the kidney. Only one case due to duodenal pathology is reported (von Friedman and Lefke, 1969), although Hoare (1973) reports a case of ureteroduodenal fistula ascribed to a duodenal ulcer. Tuberculosis was considered to be an important cause; there are, however, only 5 reported cases in the literature (*Table I*).

Chronic renal inflammatory disease accounts for the majority of cases. Of the 31 cases we have collected 23 were due to chronic infection. Fifteen of these were associated with calculus and 10 also had a perinephric abscess. Urinary obstruction appears to be important in the pathogenesis, leading to extensive perinephritis and eventual rupture into adjacent organs (Abeshouse, 1949; Arthur and Morris, 1966). An obstructing calculus may erode through into the duodenum (Pulvertaft, 1935; McEwan, 1968). Bissada et al. (1973) have found a striking increase in the incidence of associated calculus since 1945 and suggest that, since the advent of effective chemotherapy, an obstructive element is necessary in addition to virulent infection.

We consider our case to be one of chronic pyonephrosis, the pelvicalyceal system being grossly dilated with only a thin shell of renal tissue. There was no evidence of suppuration in the perinephric space and the renal pelvis was in direct apposition

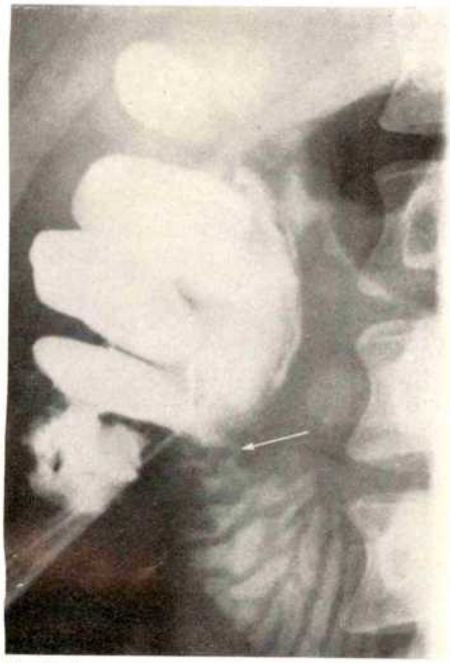

Fig. 2. Percutaneous renal puncture showing cannula in the renal pelvis. The pelvicalyceal system is clearly outlined, and the fistulous track (arrowed) can be seen. There is no flow of contrast medium down the right ureter.

with the duodenum (*Fig.* 3). It is interesting to note that no calculus was found though there was evidence of obstruction at the pelviureteric junction.

Although a few cases present with symptoms of renal disease, the commonest modes of presentation are diarrhoea, vomiting, epigastric pain and weight loss. The reflux of pus or urine into the duodenum may cause these symptoms. There have been two cases of metabolic disorder as a result of urinary reabsorption from the bowel (Boggs et al., 1961; Bissada et al., 1973). Occasionally the fistula may be entirely silent. In our case there was a past history of recurrent 'flu-like illnesses. Only the final attack brought transient symptoms and signs of pyelonephritis which prompted admission. It is uncertain when the fistulous connection with the duodenum was established. The patient showed sudden improvement on the fourth day of his first admission and this event probably signified spontaneous drainage into the duodenum.

The precise diagnosis of pyeloduodenal fistula relies on radiological investigation. The intravenous pyelogram usually shows, as in this case, a non-functioning kidney. There was no suggestion of fistula on the first IVP but after spontaneous decompression the second IVP 3 weeks later showed a poor nephrogram and contrast medium in the bowel in late films. The diagnosis is usually established by retrograde pyelography. In cases with obstruction of the ureter the fistula may be outlined by upper gastro-intestinal barium studies (Schwartz et al., 1970; Geisse and Blath, 1976). Fistulas have been shown by

micturating cystography (Bissada et al., 1973) and by identifying air in the pelvicalyceal system (Cohen et al., 1966).

The treatment of choice is surgical, nephrectomy with closure of the duodenal defect being the commonest procedure. Some authors consider surgery mandatory, but McEwan (1968) has pointed out that those patients dying whilst on conservative management probably succumb from general effects of their disease rather than from local effects of the fistula. Nevertheless, almost all cases since 1935 have undergone surgery with only two deaths (*Table I*).

Our case remained symptom-free after apparent spontaneous decompression of the kidney and treatment with antibiotics, and nephrectomy was deferred without complication. Operation was undertaken because it seemed unlikely that conservative management would cure the disease and it was impossible to exclude malignant disease without exploration.

The value of corpus–antrum border determinations in highly selective vagotomy

J. AHONEN, D. HOEPFNER-HALLIKAINEN, M. INBERG AND T. M. SCHEININ*

SUMMARY

In order to know whether the exact determination of the corpus–antrum border is of importance in highly selective vagotomy (HSV) the operation was performed on two matched groups of patients with duodenal ulcers. In group 1 (35 patients) HSV was performed using anatomical landmarks to define the distal extent of dissection. In group 2 (35 patients) HSV was performed using the same technique and then a gastrotomy was made and any remaining acid-secreting mucosa was identified using pH-metry under pentagastrin stimulation. In 22 cases secretion of acid was observed distal to the anatomically defined corpus–antrum border. In these patients a further distal division of vagal branches was done until no acid secretion was observed. Two months and 1 year after the operation, basal acid output (BAO), pentagastrin-stimulated acid output (PAO_{pg}), insulin-stimulated acid output (PAO_I) and basal serum gastrin determinations were done and compared with the corresponding preoperative data. Our results show that despite the more extensive division of the antral vagal branches in group 2, BAO and PAO_{pg} were similar in both groups postoperatively. Postoperative PAO_I was also similar. Differences were observed, however, in postoperative serum gastrin levels—group 1 42·5 ± 6·0 pmol/l and group 2 81·7 ± 7·4 pmol/l 1 year after the operation. In no cases did the more extensive dissection of antral vagal branches lead to clinical or radiological gastric stasis. Thus, if the branches of the nerves of Latarjet are used as landmarks in performing HSV, in many cases vagally innervated, acid-secreting mucosa will be left in the stomach, but apparently this is quantitatively of minor importance. On the other hand, a more extensive distal vagal dissection leads to disturbingly high postoperative serum gastrin values.

In highly selective vagotomy (HSV) the aim is to denervate the acid-secreting part of the stomach—the parietal cell mass. The extent of the distal dissection is usually based on anatomical landmarks; it can also be determined by identification, 'mapping' of the corpus–antrum border using pH-metry (Amdrup and Jensen, 1970). Whether pH-metry is really necessary is still a debatable issue (Goligher, 1974; Johnston, 1975). We have studied this question in two groups of duodenal ulcer patients subjected to highly selective vagotomy without pyloroplasty. In one group the dissection was carried out using the branches of the nerves of Latarjet as anatomical landmarks. In the second group a gastrotomy was made after a dissection based on these landmarks and the corpus–antrum border was identified by pH-metry. This was followed by extended denervation if indicated by the pH values. An assessment was made of the gastric acid secretion and basal serum gastrin values in both groups 1 year after surgery.

Patients and methods

Patients

The series consisted of consecutive patients admitted for elective surgical treatment of chronic duodenal ulcer disease. Altogether 70 patients participated in this study. In group 1 35 patients were subjected to HSV in a hospital in Turku, where the operation was carried out without intragastric mapping of the corpus–antrum border. In group 2 35 patients were subjected to similar surgery in a hospital in Helsinki, where intragastric identification of the corpus–antrum border was performed. The diagnosis of chronic duodenal ulceration was based on clinical, radiological and endoscopic findings and confirmed at operation. The indication for surgery was resistance to conservative treatment in both groups. As shown in *Table I*, the groups were satisfactorily matched with regard to age and sex distribution and preoperative secretion data.

Table I: PREOPERATIVE DATA

Group	F/M	Age (yr mean ± s.e. mean)	Acid secretion (mmol/h; mean ± s.e. mean) BAO	PAO_{pg}	Basal serum gastrin (pmol/l; mean ± s.e. mean)
1	5/30	43·9 ± 2·2	4·2 ± 0·9	39·4 ± 3·1	36·5 ± 3·1
2	8/27	43·5 ± 1·7	4·6 ± 0·7	39·1 ± 2·2	36·4 ± 4·0

F, Female; M, male.

Technique of HSV

The operation was essentially carried out according to the technique of Johnston and Wilkinson (1970). All operations were performed by the authors, who have trained together as surgeons and were originally members of the same vagotomy team. In group 1, where pH-metry was not performed, the distal extent of the dissection was determined by the distribution of the nerves of Latarjet. The end-point of denervation was located where the terminal branches of the nerves passed at right angles into the antral wall, from 6 to 8 cm (mean 7 cm) from the pylorus.

In group 2, in which intragastric mapping was always performed, a similar dissection was first carried out. An anterior gastrotomy was then made proximal to the level of the presumed corpus–antrum border. Premedication and anaesthesia excluded the use of atropine. Pentagastrin infusion (6 μg kg^{-1} h^{-1}) was started 15 min before the gastrotomy was made. Hydrochloric acid in the stomach was neutralized with 1·5 per cent sodium bicarbonate followed by washings with distilled water. The gastric mucosa was painted with Congo Red (red at pH above 5, black at pH below). To locate and delineate eventual areas of low mucosal pH a pH-meter (Radiometer, Copenhagen) was used. In the presence of mucosal areas with low pH the corresponding vagus branches were identified and cut. The washing procedure was repeated and the denervation continued, until no areas with a pH less than 5 could be detected. In 22 of the 35 patients the distal denervation had to be continued for an additional 1–5 cm (mean 2 cm). In these 22 cases the final length of innervated antrum was, on the average, 5 cm. Additional denervation was not required in 13 patients with a mean length of innervated antrum estimated as 7 cm.

Finally, in group 2, the intactness of antral motor nerve supply was assessed using a Burge stimulator (Burge and Vane, 1958). This was placed around both nerves of Latarjet and

No statistically significant difference existed between the groups at any given point.

around the freed lesser omentum. The antral peristaltic waves resulting from electrical stimulation were observed by direct vision and recorded using a rubber balloon connected to a pressure transducer and electronic recorder.

Measurement of acid secretion before and after HSV
Basal acid output (BAO) and pentagastrin-stimulated peak acid output (PAO$_{pg}$) were determined in all patients preoperatively as described by Baron (1973). An especially designed suction pump was used for collection of gastric secretions (Egnell, Stockholm). The correct location of the radio-opaque nasogastric tube was checked by radiography. For determination of BAO, gastric secretions were collected during four 15-min periods. A pentagastrin dose of 6 μg/kg body weight (Peptavlon, Imperial Chemical Industries, England) was given intramuscularly for determination of PAO$_{pg}$. Four 15-min batches of gastric juice were collected. One-millilitre samples of gastric juice were titrated with 0·01 N NaOH to pH 7 after filtration. PAO$_{pg}$ was calculated from the two highest consecutive periods after stimulation.

At 2 months and at 12 months after HSV, insulin-stimulated peak acid output (PAO$_I$) together with BAO and PAO$_{pg}$ determinations were made. An insulin dose of 0·2 U/kg body weight was given; the test was performed according to Baron (1973). The insulin response was considered positive if the acid concentration in one 15-min sample exceeded the highest basal value by 20 mmol/l or more. In addition to this original Hollander estimation, the criteria of Ross and Kay (1964) were used to distinguish between early and late positivity. PAO$_I$ was calculated from the two highest consecutive periods. BAO was not subtracted from the obtained values. Blood glucose was analysed on an autoanalyser 30 and 45 min after insulin injection using the glucose oxidase method. A decrease of blood glucose concentration to less than 35 mg/100 ml was used as the criterion of adequate insulin stimulation.

Serum gastrin
The blood samples for determination of basal serum gastrin were taken after overnight fasting and without aspiration of the stomach contents. Gastrin concentrations were determined radioimmunochemically (Yalow and Berson, 1970). The antibody used was raised in rabbits against synthetic gastrin-17. The gastrin determinations were performed before and 12 months after HSV.

Gastric emptying
The food-barium meal (altogether 350 ml) consisted of two scrambled eggs, salt, 50 ml of milk, one thick slice of bread and 100 ml of Mixobar (Astra). The ingredients were homogenized and the consistency of the meal was semi-solid (4·25 Mattson units). The emptying time was determined from hourly abdominal radiographs. The patients were upright or sitting between the examinations. The test was finished when complete emptying of the gastric contrast medium was observed. The examinations were made preoperatively and at 2 and 12 months after HSV.

Statistical methods
A Hewlett–Packard 9810 A calculator was used for calculating means and s.e. means and an unpaired *t* test program and two-tailed table for estimating probabilities.

Results

The effect of HSV on gastric acid secretion in both groups is shown in *Figs.* 1 and 2. The BAO was similar in both groups before and after vagotomy. In group 1 BAO at 2 months was 0·55 ± 0·17 (mean reduction 86·9 per cent). The corresponding values in group 2 were 0·56 ± 0·21 (mean reduction 87·8 per cent). One year after operation there was an increase in BAO in group 1 to 1·30 ± 0·32 (mean reduction 69·0 per cent) and in group 2 to 1·61 ± 0·49 (mean reduction 65·0 per cent). There were no statistically significant differences between the groups.

PAO$_{pg}$ was also very similar in both groups after HSV. At two months PAO$_{pg}$ was 11·31 ± 1·62 (mean reduction 71·3 per cent) in group 1 and 9·63 ± 1·76 (mean reduction 75·4 per cent) in group 2. There was a slight subsequent increase in the pentagastrin response during the first year to 18·71 ± 2·22 (mean reduction 52·5 per cent) in group 1 and to 14·49 ± 2·19 (mean reduction 62·9 per cent) in group 2. No statistical differences were observed between the groups.

Fiberoptic Endoscopes

As regards the postoperative insulin-stimulated gastric acid secretion, the peak acid outputs were again surprisingly similar in both groups. In both groups a definite increase of $\mathrm{PAO_I}$ occurred between 2 and 12 months after HSV (*Table II*). The results of postoperative insulin tests, according to the criteria of Ross and Kay (1964) are shown in *Table III*. There were no early positive responses either at 2 months or at 1 year after HSV in the groups. However, late positivity was twice as common in group 2 as in group 1. This difference was not present in the early postoperative determinations, but became evident 1 year after surgery.

A comparison between postoperative basal serum gastrin values in the groups showed one definite difference between the groups (*Table IV*). After HSV the values increased significantly in both groups ($P<0{\cdot}05$ in group 1, $P<0{\cdot}005$ in group 2), but the mean gastrin value 1 year after operation was significantly higher ($P<0{\cdot}005$) in group 2 than in group 1.

Postoperatively, none of the patients in either group showed clinical signs of gastric retention. Measurements of gastric emptying time showed no significant differences between pre- and postoperative values. The mean preoperative emptying time was 3·3 h, as compared with 3·4 h 2 months and 3·5 h 12 months respectively after HSV.

Discussion

Most surgeons use the distribution of branches of the nerves of Latarjet to define the corpus–antrum boundary when they perform HSV. It has been shown, however, for instance by Poppen et al. (1976) who took mucosal biopsies through a gastrotomy, that this landmark corresponds to the corpus–antrum border in only 47 per cent of patients. In the present study we observed that in 22 of the 35 cases the branching of the nerves of Latarjet did not define the boundary between acid-secreting and antral mucosa. The difference could be due to the fact that the distance between mucosal biopsies in Poppen's study was 2 cm while our method allowed continuous monitoring of the mucosa. In any case, it appears to be certain that the distribution of the branches of the nerve of Latarjet does not always define the boundary between acid-secreting and antrum-type mucosa. This means that, in a certain percentage of patients, innervated parietal-cell-containing mucosa remains in the stomach when the HSV is performed using these landmarks. Does this have any clinical significance?

Our results show that there were no differences in the postoperative gastric acid secretions of the two groups when anatomical landmarks were used or the boundary was defined exactly using intraoperative measurements. Unfortunately, this study was not a properly randomized investigation but the preoperative data showed that the groups were well matched. Also, we tried to standardize our operative technique by ensuring that both groups of surgeons used the same anatomical landmarks in determining the distal end-point of dissection. Measurements on acid secretion were done in a similar way by nurses who had had several years' experience and gastrin determinations were carried out in the same laboratory. Thus, we believe we can conclude that intraoperative mapping is not needed to define the corpus–antrum border in HSV because the reduction in acid secretion postoperatively is similar whether anatomical landmarks or intraoperative measurements are used. Also, our results on the effect of HSV on gastric acid secretion are quite comparable with those reported by others (Johnston, 1975).

Our experience with pH-metry also indicates that complete denervation of acid-secreting cells in at least some patients leads to cutting of nerve branches that anatomically could be considered as 'antral'. This is at variance with the observations of Amdrup and Jensen (1970) who, using intragastric pH-metry, found that the corpus–antrum border was situated quite high—8–9 cm above the pylorus. It is difficult to explain why our experience has been different. During our mapping procedures we could confirm the observations of Grassi (1971) and Larsson (1973) that division of vagal branches to the acid-secreting area renders the mucosa temporarily unresponsive to pentagastrin stimulation.

In both groups a clear rise in basal serum gastrin (the stomach was not aspirated before blood sampling) following highly selective vagotomy was observed. This has been reported by others too (for review *see* Stadil, 1977). The mean postoperative serum gastrin was much lower in the unmapped group than in the group in which mapping was performed. Our upper normal value is 50 pmol/l, so the mean serum gastrin concentration in group 2 is clearly pathological. This could be thought to be due to gastric retention in these patients. There were no clinical signs of retention, however, nor did the X-ray study show any retention.

Malmstroem et al. (1977) have suggested that, in man, the antral vagal branches would have an inhibitory effect on gastrin release, which could explain those authors' observation that truncal vagotomy is followed by increased serum gastrin and increased antral gastrin concentrations. In our group 2 a more extensive antral division of the vagal branches was performed. If these branches have an inhibitory effect on gastrin release, that would result in higher postoperative serum gastrin values. The clinical consequences of hypergastrinaemia (as measured by radioimmunoassay) are not known, but this must be considered as an undesirable result. As the effects of the operation on acid secretion were similar in both groups studied, we conclude that mapping of the corpus–antrum border is not needed in highly selective vagotomy.

University of Papua New Guinea

Most medical school libraries in the developed world have a stock of 30 000 books or more. In addition, they are likely to have the support of other biomedical libraries within easy reach either physically or by telephone or telex.

In Papua New Guinea there is a medical school library of 10 000 volumes. This does not just cater for the staff and students of the faculty; it is *de facto* the national medical library. As such, it serves the needs of all medical, dental, paramedical and research personnel over a large, remote and inaccessible area. Many of these work in isolated hospitals whose only contact with the capital is the airstrip and the radio or telephone. The challenge of providing a medical library and information service to the nation is one which the library is happy to accept, but its resources are too slender to be effective. In addition, there will soon be a new dental school without special funds for extra book provision.

The immediate need is to improve the library's bookstock, increase the range of journals and provide more extensive sets of back runs. The present and future medical profession of Papua New Guinea seek assistance.

The address is Medical Faculty Library, P.O. Box 5623, Boroko, Papua New Guinea.

Results of proximal gastric vagotomy over 1–5 years in a district general hospital

D. A. MAKEY, F. I. TOVEY AND R. J. HEALD*

SUMMARY

One hundred and seventy-three patients underwent proximal gastric vagotomy for duodenal ulceration over a 6-year period. One hundred and fifteen of these have been followed up for 1–5 years. The operative mortality was nil and the result was satisfactory in 91 per cent. The incidence of side effects was small, notably that of dumping being 2·4 per cent and of diarrhoea, 3·6 per cent. Incidence of postoperative heartburn was reduced from 13 per cent to 4 per cent by the introduction of hepatic interposition.

The incidence of recurrent ulceration was 5·1 per cent after an average interval of 2 years and that of new gastric ulceration 2·6 per cent after an average of 4 years. There were no recurrent ulcers in those who had peroperative Burge tests, although secretory studies showed no difference between those tested and those not tested. Most recurrences occurred in the earliest cases operated on before Burge testing was introduced and when only 2 cm of the lower oesophagus were exposed.

SEVERAL centres have reported varying recurrence rates after proximal gastric vagotomy (Johnston and Wilkinson, 1970; Grassi et al., 1973; Amdrup et al., 1974; Kronborg and Madsen, 1975; Amdrup et al., 1977; Holst-Christensen, 1977; Dorricott et al., 1978; Goligher et al., 1978).

Our aim is to present the results of elective proximal gastric vagotomy (PGV) for duodenal ulcer in a district general hospital and to assess its efficiency in this situation.

Patients and methods

One hundred and seventy-three patients with duodenal ulcer have undergone PGV without drainage in Basingstoke District Hospital since April 1971. One hundred and fifteen of these have now been followed up for 1–5 years.

All patients had a duodenal ulcer demonstrated radiologically, endoscopically or both. All had elective or semi-elective operations following bleeding that had stopped.

The patients fell into two groups according to the practice of the operating team concerned (*Table I*).

The majority of patients in group 1 had pre- and post-operative pentagastrin tests (3 months or more after PGV) and peroperative Burge tests, except for the first 15 cases which were operated upon before the Burge test was introduced, these having insulin tests instead (again 3 months post-operatively). All the operations were performed by one surgeon (F. I. T.).

Group 2 cases had no acid studies carried out and no per-operative monitoring. The operations were performed by 5 surgeons of differing experience, although just over half were done by one experienced surgeon (R. J. H.).

The operative technique was basically the same in each group. The dissection was taken from the crow's foot up the lesser curve, 'ring barking' the oesophagus for 4–5 cm, with the exception of the first 15 cases in group 1 in which the dissection was taken about 2 cm on to the oesophagus, as originally described by Amdrup and Jensen (1970). The only minor difference was that group 2 patients routinely had division of the left triangular ligament and interposition of the left lobe of the liver between the freed lesser omentum and the bared lesser curve at the end of the procedure.

Table I: DURATION OF FOLLOW-UP FOR EACH GROUP OF PATIENTS

	Duration of follow-up (yr) 5	4	3	2	1	<1	No record
Group 1	14	13	17	11	18	17	1
Group 2	—	5	15	10	12	35	5
Total	14	18	32	21	30	52	6

Table II: OCCURRENCE OF SYMPTOMS AND VISICK GRADING AT TIME OF FOLLOW-UP

	No. of patients	%	
Symptoms			
Non-ulcer dyspepsia	21	12	
Heartburn	15	9	
Food vomiting	2	1·2	
Bile vomiting	—	—	
Small meals	10	6	
Dumping (early and late)	4	2·4	
Diarrhoea	6	3·6	
Grades			
1 Asymptomatic	115	69	}91
2 Trivial symptoms	37	22	
3 More persistent symptoms but no ulcer	6	3·6	
4 Recurrence (plus gastric ulcers)	9	5·4	

Secretory studies

All nasogastric tubes were radiologically positioned in the stomach opposite the angulus.

Pentagastrin tests: Resting juice was collected over one hour for the basal acid output, followed by the injection of pentagastrin (6 μg/kg) intramuscularly and the collection of gastric juice for a further hour to obtain the maximal acid output. Histamine (4 mg/kg) was used in the first 15 cases instead of pentagastrin.

Insulin tests: Four fasting samples at 15 min intervals were taken and the sample with the highest concentration was taken for the basal acid concentration. The samples were pooled for the basal acid output. Soluble insulin (0·15 U/kg) was given intravenously and aspirates collected at 15-min intervals for 2 h. The insulin test was deemed positive if three or more of the following criteria were positive:

1. A rise of 20 mmol/l over basal concentration in either the first or second hour (Hollander, 1946, 1948).
2. A basal acid output of more than 2 mmol/h (Bachrach, 1962).
3. An increase of more than 2 mmol in output over the basal hour in either of the post-insulin hours (Bank et al., 1967).
4. An increasing volume after insulin (Waddell, 1957).
5. A fall of less than 60 per cent in maximal acid output with either pentagastrin or histamine.

The Burge tests were all conducted according to the method of Burge and Vane (1958). All patients were followed up routinely at 3 months, 6 months and yearly thereafter. Defaulters were sent a questionnaire, which yielded a good response. This resulted in 88 per cent of patients having completely up-to-date records, follow-up being incomplete in 9 per cent and 3 per cent being untraceable since their operation.

Table III: RELATIONSHIP OF THE FALL IN BAO AND MAO TO THE OPERATIVE RESULTS

	Average age (yr)	Average duration of history (yr)	Acid output (mmol HCl) Preop. BAO	MAO	Postop. BAO	MAO	% fall BAO	MAO
Satisfactory result ($n = 42$)	45	10	5·1	28·5	1·14	11·4	78	60
Recurrence ($n = 4$)	32	9	7·3	30	3	17·5	59	42
Non-ulcer dyspepsia ($n = 8$)	40	8	4·6	28·3	0·96	10·6	79	62
First 15 in group 1 ($n = 11$)	42	13	5·9	31	2·3	13	61	60

Table IV: FALLS IN BAO AND MAO WITH AND WITHOUT THE BURGE PEROPERATIVE VAGAL STIMULATION TEST

	Acid output (mmol HCl) Preop. BAO	MAO	Postop. BAO	MAO	% fall BAO	MAO
Burge test ($n = 28$)	4·9	30	1·05	12·1	78	60
No Burge test ($n = 26$)	5·4	29	1·35	10·9	75	62

Preoperative symptoms were assessed retrospectively for length of ulcer history, periodicity and relief by food. Postoperative side effects were specifically asked for, as was recurrent dyspepsia. Recurrent ulceration was proved by endoscopy and/or laparotomy with the exception of one gastric ulcer that was shown by a barium meal.

Results

The operative mortality was nil. There was no case of lesser curve necrosis. Splenectomy was necessary in 3 patients in whom the spleen was damaged and in 2 patients small oesophageal tears were repaired, otherwise there were no serious operative complications. Postoperative recovery was invariably rapid. Nasogastric tubes were used in most of group 1 patients but not in group 2 and the tubes were generally removed on the second day. Fluids were started early and a light diet was commenced on the third day. No postoperative gastric retention was seen except in one patient who probably had significant pyloric stenosis before operation and on whom no definitive pyloric procedure was undertaken at surgery.

The results were divided into four groups corresponding approximately to Visick grading. The overall incidence of dumping, early or late, was 2·4 per cent (4 cases), which was very mild in all cases and required no treatment. Six patients (3·6 per cent) had episodic diarrhoea, but not severe enough to warrant treatment. Persistent anaemia, weight loss or bile vomiting were not seen. Fifteen patients had heartburn or reflux, of whom 12 were in group 1 and had not had hepatic interposition (*Table II*).

In estimating recurrence rates, only the group with a 1–5-year follow-up has been considered. Thirty patients complained at some stage of recurrent epigastric pain. Six of these (5·1 per cent) were found to have a recurrent duodenal ulcer and 3 (2·6 per cent) a new gastric ulcer. Of the remaining 21, 6 had negative endoscopic examination, 2 negative barium meals and 13 only transient dyspepsia for a few weeks, not severe enough to merit investigation or treatment.

Two of the recurrent duodenal ulcers presented within the first year, 2 at 2 years and 2 at 3 years; all were in male patients. Four of the recurrences were among the first 15 patients in group 1. Further surgery was required in 3 of these (1 revision vagotomy, 1 truncal vagotomy and antrectomy and 1 Polya gastrectomy) and in the other patient the ulcer healed and has not recurred. One patient in group 2 has refused further surgery and one has only mild, infrequent symptoms. None of these patients has developed any complications.

The 3 gastric ulcers occurred at between 3 and 5 years. Two of these ulcers have been shown by endoscopy and 1 by radiology to have healed on medical treatment (2 with cimetidine, 1 with carbenoxolone) and the patients at present have no pain.

There were 54 patients in whom complete pre- and postoperative pentagastrin tests had been performed, including 4 patients with recurrence and 8 from the group of 21 patients already mentioned who had non-ulcer dyspepsia (*Table III*).

The acid fall was less in those with recurrence as a group, although the individual MAO reductions were not predictive in each case (20 per cent, 40 per cent, 56 per cent and 58 per cent). Similarly, those with a satisfactory result as a group had a 60 per cent MAO fall, but there were several individuals with much smaller reductions. The groups with dyspepsia and the first 15 patients in group 1 had results almost identical to those of the satisfactory group.

Eleven of the first 15 patients in group 1 had had insulin tests, which in 5 showed incomplete vagotomy (4 first- and second-hour responses and 1 second-hour response only). Three of these patients developed recurrent ulceration. In addition, the patient with a transient recurrence had an insulin test that was negative at 5 months but became positive (second-hour response but with a low MAO with histamine) at 18 months. The insulin tests, though fewer in number, seem to have equated better with recurrence than the pentagastrin tests, because several of the later cases showed less than 60 per cent reduction in MAO without recurrence.

Burge test

The Burge test was performed in 57 patients. In 5 it was technically unsatisfactory, in 3 no response was obtained and in 2 the response could not be abolished despite repeated further dissections and was thought to be somatic. In 47 cases, therefore, an apparently complete vagotomy was obtained, resulting in no recurrent ulcers, 1 gastric ulcer and 8 cases of non-ulcer dyspepsia. Twenty-eight of these 47 cases also had pentagastrin tests and the results were compared with those in 26 patients who had not had the Burge test. This showed no significant difference in acid fall between these two groups (*Table IV*).

Discussion

To establish its place as the operation of choice for duodenal ulceration PGV must show its superiority over other procedures in terms of operative mortality and lack of side effects—especially dumping—and yet have an acceptably low recurrence rate.

The one cloud on the horizon as far as operative mortality is concerned has been lesser curve necrosis. Varying incidences of this often fatal complication have been reported—1·4 per 1000 in Johnston's (1975) survey. It has been suggested that this can be avoided by careful technique and avoidance of diathermy (Heffernan, 1976), or by reperitonealization of the lesser curve (Halvorsen et al., 1975). Fortunately, there have been no instances of gastric necrosis in our series.

Side effects

The dumping, bile vomiting and late nutritional defects found in some patients after gastrectomy still occur to a lesser extent after truncal vagotomy and drainage. If they are caused by abnormal emptying due to the drainage procedure rather than the vagotomy, then we would expect their incidence to fall almost to nil with PGV. Bilateral selective vagotomy with drainage (de Miguel, 1974) reduced the incidence of diarrhoea from 40 to 20 per cent but did not abolish it completely. Following PGV Johnston reported an incidence of only 2 per cent (Johnston et al., 1972). Our series also shows a low incidence of diarrhoea (3·6 per cent), dumping (2·4 per cent) and bile vomiting (nil).

In addition, the lesser incidence of heartburn in group 2 suggests that heartburn may be reduced by employing hepatic interposition. This procedure was done initially to prevent reinnervation of the lesser curve. An added bonus may be that late reoperation, if required, would be easier.

The overall symptomatic results of PGV have been good, with 91 per cent of patients in Visick grades 1 and 2. The 6 poor results (grade 3) are all due to persistent pain, and 2 of these patients are probably neurotic as no definite ulcer has been found at operation. Two patients probably had an erroneous original diagnosis (by barium meal only). In addition, 4 of the 6 had atypical histories. This emphasizes the importance of eliciting a good history of periodicity and relief by food, and confirmation of the diagnosis by endoscopy as well as by barium meal examination when the history is atypical.

Recurrence

One of the drawbacks of vagotomy that leads to its inferior Visick grading compared with gastrectomy (Goligher et al., 1972) has been the high recurrence rate. It is disputed whether this is due to the intrinsic inability of denervation alone to reduce acid sufficiently to cure an ulcer in all patients, or merely to a high incidence of incomplete vagotomy.

Some authors have tried tailoring their surgery according to the preoperative BAO (Orr, 1962) or to the MAO (Bruce et al., 1959; Small et al., 1967; Robbs et al., 1973), usually adding an antrectomy to the vagotomy when the MAO is above a certain level (25 mmol, Robbs; 50 mmol, Small). In addition, Kronborg (1972, 1974) has persistently demonstrated relationships between risk of recurrence and pre- and postoperative acid secretion.

On the other hand, other authors (Holt and Lythgoe, 1961; Clark et al., 1964) found preoperative acid studies to have no prognostic significance. Tovey et al. (1968) found the biggest falls in MAO after truncal and selective vagotomy in those patients with the highest preoperative acid levels. Johnston et al. (1975) have suggested that PGV alone is sufficient even for hypersecretors (MAO more than 50 mmol/h in men) so long as incomplete vagotomy can be avoided. Burge also believed that almost all recurrences after vagotomy were due to leaving intact vagal fibres, commonly small accessory posterior trunks in the case of truncal vagotomy (Burge et al., 1970). Although good figures for selective vagotomy have been reported (Griffith et al., 1972; Amdrup, 1973; de Miguel, 1974), the fact that no completely standardized technique was developed probably led to many incomplete vagotomies in other hands.

With PGV, however, as long as the dissection is taken sufficiently high on the oesophagus, there appears to be less risk of an incomplete vagotomy; indeed, the danger with some techniques (Burge and Frohn, 1969) may be of damaging the main posterior vagus inadvertently. If a complete vagotomy will cure almost any ulcer, great pains must be taken to achieve this. The incidence of incomplete vagotomy fell during this study—possibly aided by the Burge test—in group 1. In this group, however, the introduction of the Burge test coincided with a more extensive dissection of the lower oesophagus.

The fact that the pentagastrin tests with and without the Burge vagotometer reveal no differences reflects either the fallibility of secretory studies or, perhaps, indicates that complete vagotomy is now being achieved without Burge testing.

It seems appropriate, therefore, especially for surgeons learning the technique of proximal gastric vagotomy, to have some form of quality control, at least early on. The best is probably the Burge test, as the vagotomy, if incomplete, can be completed at the time of operation. One of the present authors (F. I. T.) continues to use the Burge test because about 1 in 3 of the patients has an initial positive response despite an apparently complete dissection. The division of further strands of possible nerve tissue usually produces a negative response. Pre- and postoperative acid studies are also helpful, but less so because the result is not known until 3 months later. Once the technique has been mastered, however, these controls may be unnecessary, as an adequate vagotomy may be intrinsically easier to achieve with proximal gastric vagotomy than with other forms of vagotomy.

mightier than the knife

Now there is a practical alternative to surgery for calcium renal lithiasis: long-term prophylaxis with Zyloric.

Zyloric has proved effective in preventing and treating calcium renal lithiasis in patients with raised serum or urinary uric acid.

In a recent trial,[1] 48 patients with hyperuricosuria were treated with Zyloric for an average of 3.88 patient years. The number of renal stones predicted for this period was 94.9. The actual number of stones formed was 8. Prior to treatment with Zyloric, half of these patients were hospitalised because of stone disease.

A leading article[2] in the British Medical Journal, commenting on another clinical paper[3] stated "...the only criterion of success in the treatment of calcium stone disease is total cessation of stone formation. By this criterion, allopurinol (Zyloric) was greatly superior to the placebo."

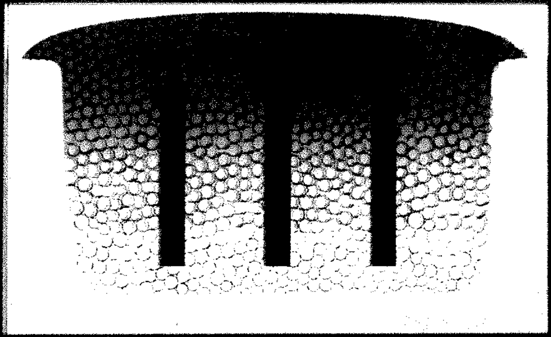
Creating the healing environ

It's where a wound is continuously cleansed by thousands of individual beads; exudate is effectively absorbed faster than the wound's ability to secrete it.

It's where bacteria and wound debris are actively transported away from the wound.

And substances responsible for inflammation, oedema and crust formation are separated from the delicate wound surface.

Debrisan beads create such an environment. Without any reported sensitization.



DEBRI

The totally new concept for cleansing

Debrisan beads
magnified x30 under blue transmitted
and red incident light

Prescribing Information

Presentation
Sterile. Straw-coloured spherical beads of dextranomer of 0.1 – 0.3mm in diameter, packed in sterile castors containing 60g and sachets containing 4g.

Uses
Debrisan is a dressing for moist, small area burns, wounds and indolent ulcers whether clean or infected. Since it promotes the formation of granulation tissue it may be used to prepare burns for grafting.

Dosage and Administration
The wound must first be washed with saline and any loose debris removed. Moisture is left in the wound to ensure hydration of the Debrisan which is in direct contact with the wound surface. Debrisan is then poured onto the wound to a depth of 3mm. A piece of lint or Melolin is then bandaged over the dressing to hold the Debrisan in place. Before the layer is saturated – this is usually evident by discolouration of the whole layer – the Debrisan is rinsed off with saline and a new layer applied. Initially a twice daily change may be necessary, but after a few days, the frequency can often be reduced to once a day. Shallow wounds, or those in awkward positions, may be dressed more easily by mixing four parts of Debrisan with one part of glycerol to form a stiff paste. This may be spread into the wound with a spatula to a depth of 3mm or more. Dressing continues as above. The paste should be prepared freshly at each application.
Full instructions for use are enclosed with each pack. Treated in this manner the wound will remain soft and pliable during healing.

Contra-Indications, Warnings, etc.
1) Do not leave Debrisan for more than 24 hours on wounds with a very low exudation rate as it may dry and form a crust which may be difficult to wash off.
2) Occlusive dressings may lead to maceration of skin around the wound under treatment.
3) When deep infected wounds are treated, care must be taken to wash Debrisan from the depths of the wound.
4) No side-effects have been reported.

Warning
Debrisan spillage can render surfaces very slippery. Clear spillages promptly.

Caution
In order to avoid cross contamination it is recommended that the contents of a castor or sachet be confined to the treatment of a [illegible] one day.

Pharmaceutical [illegible]
Keep in a dry place [illegible] containers.

Package Quantity
Castors of 60g. Also available [illegible] sachets in packs of 7 sachets.

Basic N.H.S. Price:
60g castor £19.75
7 x 4g sachets £9.75
Product Licence No:
0009/0021

ment of the future.

By a unique mechanical action Debrisan removes from the wound those substances which normally complicate wound healing.

Pain and malodour are quickly reduced. Healing can now occur in an ideal environment. Fast. And often when all other approaches have failed.

Use Debrisan on all moist, small area burns, wounds and indolent ulcers whether clean or infected.

Patients can enjoy the benefits of the healing environment of the future. Today.

Highly selective vagotomy with excision of the ulcer compared with gastrectomy for gastric ulcer in a randomized trial

H. L. DUTHIE AND C. J. BRANSOM*

SUMMARY

Fifty-six patients with benign gastric ulcer of the body of the stomach have been entered into a randomized trial of highly selective vagotomy with excision of the ulcer (HSVE) (26 cases) against standard Billroth I partial gastrectomy (BI) (30 cases). The operations were carried out by all grades of surgical staff. No patient died within 1 month of operation. Postoperative morbidity was greater after gastrectomy than after HSVE. At an average follow-up of about 4 years, functional results according to a modified Visick classification were similar in both groups, with about 75 per cent good results. Two recurrent ulcers occurred after gastrectomy (7 per cent) and 4 after HSVE (15 per cent). Neither operation has a distinct advantage at this stage.

SIMPLE gastric ulcer of the body of the stomach is usually treated by partial gastrectomy with gastroduodenal (Billroth I) anastomosis when the patient's symptoms warrant surgery. This operation has been reported to have a recurrence rate of 0–5 per cent in various series (Duthie, 1970). Other postgastrectomy symptoms occur, although fewer than after gastrojejunal (Polya) anastomosis. Many of the postprandial symptoms after gastrectomy are attributed to lack of control of emptying. Attempts have been made to remedy this by forms of 'pylorus-preserving' gastrectomy, which have had excellent results with no recurrent ulcers in 60 patients followed for 1–9 years (Sekine et al., 1975). Other groups have not been able to reproduce these results, with either an unacceptably high recurrence rate at 13 per cent (Jorgensen et al., 1974) or a poor symptomatic result (Buhl and Campbell, 1974). Our approach to retention of some control of gastric emptying has been to leave the innervated antrum *in situ* by performing a highly selective vagotomy (Amdrup and Jensen, 1970; Johnston and Wilkinson, 1970). We already have experience of a controlled comparison of truncal vagotomy and pyloroplasty versus partial gastrectomy for gastric ulcer in 100 patients, and we found no significant symptomatic difference between these two operations after 5 years (Duthie and Kwong, 1973). A similar result was found by Madsen et al. (1976). It was hoped that the avoidance of pyloroplasty in the present study would improve the results of the more conservative procedure. In addition, a full-thickness excision of the ulcer and a surrounding 1 cm of gastric wall has been done to ensure complete histology and also because it may improve the chances of avoiding recurrence (Daniels and Strachan, 1973).

Patients and methods

From July 1971 to July 1977 56 patients entered the trial: all had benign gastric ulceration in the body of the stomach, prepyloric ulcers and combined gastric and duodenal ulcers being excluded. At laparotomy a decision was made as to whether the patients were equally suitable for highly selective vagotomy plus full-thickness excision of the ulcer (HSVE) or Billroth I partial gastrectomy (BI). Six patients were excluded from the trial because they were found to be unsuitable for HSVE, mainly because the ulcer was so placed as to make excision impossible without denervating the antrum.

In HSVE the surgical technique employed was similar to that of Johnston et al. (1972) except that those authors opened the stomach opposite the ulcer to perform an excision biopsy, leaving the ulcer base intact, whereas we excised the ulcer-bearing area from the serosal side. A standard partial gastrectomy with gastroduodenal anastomosis (BI) comprised removal of two-thirds of the stomach.

The 56 patients in the trial were randomized with precautions to ensure equal sex distribution. In those having HSVE the vagal denervation was completed before the excision of the ulcer, which was submitted to immediate histology. No cancer was found at this stage. In the event of malignancy it would have been easy to proceed to gastrectomy, as much of the mobilization would have already been completed. The operations were performed by surgeons in training and by consultant surgeons (30 by consultants; 15 by senior registrars or equivalent; 11 by registrars or equivalent).

An insulin test of gastric acid secretion was performed in 11 patients (42 per cent) 5 days to 27 months after HSVE: this small percentage is due to the fact that many of the women in the series either refused to attempt the test or failed to complete it. After three 15-min collections of basal acid secretions, soluble insulin (0·2 i.u./kg body weight) was injected intravenously and eight further 15-min samples were collected. The tests were performed with the patient semi-recumbent on the left side after a nasogastric tube had been positioned along the greater curvature of the stomach under radiological control. Losses through the pylorus and duodenal reflux were not measured. The response to insulin was calculated as the difference between the basal acid output (BAO) and the peak acid output after insulin (PAO_I) and also expressed as early or late positive using modified Hollander criteria (Johnston et al., 1967).

The patients were interviewed at 3, 6 and 12 months and annually thereafter. The interviewer did not have knowledge of the type of operation performed. Functional results were graded according to a modification of the Visick classification: grade 1, no gastric symptoms; grade 2, mild symptoms easily controlled by slight adjustments to diet or way of life; grade 3, moderate symptoms not controlled by simple manoeuvres and not interfering with social or economic life; grade 4, symptoms as bad as or worse than before operation (patients having recurrent ulceration at any time were assessed as grade 4).

Questions were asked routinely concerning the following symptoms: epigastric fullness, bilious vomiting, food vomiting, early dumping, late dumping, flatulence, heartburn, dysphagia and bowel habit. The severity of these symptoms was estimated in four grades. More reliance can be placed on the *incidence* of symptoms than on their grading (DeDombal et al., 1974).

Results

No patient died within 1 month of operation. HSVE was performed in 26 patients and gastrectomy in 30 patients. The groups were comparable in age (HSVE 53·6 yr, BI mean 56·2 yr) and sex distribution. Six patients have died in the follow-up period, 3 in each operative group. None of the deaths was related to peptic ulcer disease; 3 died of myocardial infarction, 1 of a cerebrovascular accident, 1 of cancer of the pancreas and 1 of bronchopneumonia. These six are included in the morbidity figures but not in the follow-up results, except the one who had a recurrent ulcer. Postoperative morbidity was statistically significantly greater after gastrectomy (*Table I*) but only at the 5 per cent level. Comparison of percentage functional results according to the modified Visick classification at a mean follow-up of about 3 years and about 4 years shows no statistically significant differences (*Table II*), but there are more excellent (grade 1) results and also more grade 4 results after HSVE. If the top two and the bottom two groups of the Visick classification are combined, the results are very similar (*Table II*), with good results in 74–78 per cent of cases. The unsatisfactory results are detailed in *Table III*. Recurrent ulceration has been found in 4 patients after HSVE (15 per cent) and in 2 patients after gastrectomy (7 per cent), 1 having died (*Table IV*) of bronchopneumonia. A partial gastrectomy has been performed in 3 patients after HSVE and in 1 from the gastrectomy group a higher gastrectomy was done with a vagotomy. The results in the small percentage of patients who underwent insulin testing do not permit any conclusions about the value of the response in assessing the risks of recurrence (*Table V*). Most symptoms recorded after operation were more frequent after BI gastrectomy than after HSVE. This difference was only probably statistically significant for postprandial nausea (*Table VI*). It must be remembered that most of these symptoms were mild, and nausea contributed to only 1 patient being placed in Visick grade 3.

Discussion

At this early stage in the assessment of the procedures no clear lead can be given as to the eventual outcome. The symptomatic results, with about three-quarters having a good result, are similar to those in other reports (Semb, 1978) and indicate the practicability of using either operation for the surgical management of gastric ulcer. The larger number of patients with no symptoms after HSVE at 3 years did not reach statistical significance and was in contradiction to the early results in our previous comparison of truncal vagotomy and pyloroplasty with Billroth I partial gastrectomy when the gastrectomy patients had superior results 3 years postoperatively, although this advantage was lost by the 5-year follow-up (Duthie and Kwong, 1973). It is interesting that HSVE had lost its potential advantage by the 4-year follow-up stage in the present study.

The technique of highly selective vagotomy is well established in this unit, with over 200 operations having been performed by all grades of staff. Thus the cases reported here have not been treated solely by consultants but also by surgeons in training. If a procedure is to be acceptable on a broad basis it must be tested on a similar scale. The mobilization of the lesser curvature of the stomach in HSVE renders the excision of the ulcer straightforward, except in those cases where it is to be found at the incisura, when the full operation with ulcer excision becomes impossible.

Table VI: POSTOPERATIVE SYMPTOMS: PERCENTAGE INCIDENCE

	Billroth I gastrectomy	Highly selective vagotomy
Ulcer pain*	15	5
Nausea	31**	0†
Bile vomiting	19	5
Food vomiting	15	0
Epigastric fullness	62	40
Early dumping	27	5
Late dumping	12	0
Heartburn	40	35
Flatulence	54	40
Dysphagia	0	10
Episodic diarrhoea	35	15

* Excludes those with proved recurrent ulcer.

† Difference statistically significant ($P<0·05$).

Although ulcer recurrence is largely prevented after HSVE, it can only be as a result of the reduction in the production of acid/pepsin by the stomach since nothing specific has been done to change the amount of biliary reflux, which is thought to play an important part in the aetiology of gastric ulcer (Rhodes and Calcraft, 1973).

The higher percentage (15 per cent) of recurrent ulceration after HSVE is disappointing, although it does not reach statistical significance over gastrectomy (7 per cent). It is higher than the recurrence rate in our series comparing truncal vagotomy and pyloroplasty with gastrectomy (Duthie and Kwong, 1973) but, if one may be permitted to compare different series, not significantly higher. By analogy with recurrent duodenal ulceration after vagotomy, one of the recurrent ulcers could be attributed to incomplete denervation, as shown by the early positive insulin test, but we have not enough information to give any prognostic significance to gastric responses to insulin hypoglycaemia in this series. The number of recurrences may increase, as several patients have had symptoms which they liken to ulcer pain, although endoscopy has shown normal appearances. We already have the experience of two subjects having mild intermittent symptoms for 3 years before a firm diagnosis of recurrent ulcer was established.

By insisting on the excision of the ulcer-bearing area we have abandoned one of the advantages of conservative surgery in the case of the ulcer situated high on the lesser curve, but in return, we have gained the security of a histological study of the full ulcer area.

Thus, from a technical as well as a functional point of view there seems to be no pressing indication to change to highly selective vagotomy with excision in place of Billroth I partial gastrectomy for the surgical treatment of benign gastric ulcer of the body of the stomach.

Long term follow-up of patients with gastric ulcers treated by vagotomy, pyloroplasty and ulcerectomy

DAVID CADE AND DAVID ALLAN*

SUMMARY

Vagotomy and pyloroplasty with excision of the ulcer has been performed in a series of 90 patients with benign gastric ulcers. Long term follow-up has shown only 2 patients with recurrent ulceration. Fifty-eight patients with more than 2 years' follow-up attended for personal interview, of whom 96 per cent had a satisfactory result.

In the surgery of benign gastric ulcers, vagotomy and pyloroplasty alone has been associated with a recurrence rate of 5–36 per cent, and in most centres partial gastrectomy has held pride of place in the treatment of gastric ulcers. There is, however, a tendency for gastric ulcers to inhabit a particular site in any one stomach, and if excision of the ulcer is performed at the same time as a vagotomy and drainage procedure, then recurrence rates decrease.

Patients and methods

In the present series, 62 patients were reviewed in 1971 (Daniels and Strachan, 1973). These patients plus a further 28 make up the series of 90 patients. There has been one instance of recurrent gastric ulcer and one of recurrent duodenal ulcer.

Technique

Truncal vagotomy has been the operation of choice. The only patient to have a selective vagotomy later developed a recurrent gastric ulcer. Lesser curve ulcers are excised by opening the stomach close to the ulcer and excising the ulcer from the mucosal surface. The resulting defect is sutured in two layers with chromic catgut. If there is much surrounding thickening it is not always possible to invert the seromuscular layer. A posterior ulcer cannot always be approached via the lesser sac, in which case the ulcer is excised through an anterior gastrotomy.

Results

Ninety patients (57 males, 33 females) in Barrow in Furness have had this operation as the primary procedure between 1963 and 1975. The average age of the patients was 55·5 years (*Table I*).

Thirteen patients presented with bleeding and 5 patients presented with a perforation, all requiring urgent surgery. Twenty-one patients had an associated duodenal ulcer or evidence of there having been one in the past. Four patients had prepyloric ulcers.

Table I: DETAILS OF THE PATIENT SERIES

Died postoperatively	4	
Died subsequently (unrelated causes)	13	
Visick grade 1 (seen) (2 yr follow-up)	3	
Visick grade 1 (seen)	51	96% of long term follow-up patients attending personal interview
Visick grade 2 (seen)	5	
Visick grade 3 (seen)	2	
GP follow-up	4	
Untraceable	6	
Recurrence	2*	
Total	90	

* One gastric and one duodenal ulcer.

Four patients died postoperatively: 2 from pulmonary emboli, 1 from a coronary thrombosis and 1 from bronchopneumonia complicating a possible staphylococcal enteritis (Daniels and Strachan, 1973).

Thirteen patients have died subsequent to the operation—all of unrelated causes: 3 of this group were followed up for less than 2 years and all were Visick grade 1 when last seen. The average follow-up period of the remaining 10 patients was 5 years, when 8 were classified as Visick grade 1 and 1 was Visick grade 2. The tenth patient died 4 years after his operation from a carcinoma of the stomach. The original histology was confirmed as benign.

Six patients were untraceable: 5 had been followed up for 1–4 years and 4 had been classified as Visick 1 grade 1 and 1 as Visick grade 2. The sixth was an Indian seaman who had no follow-up.

Four patients were unable to attend for review, but their general practitioners were contacted and none of these patients appeared to have any gastric symptoms.

Sixty-one patients attended a specially arranged out-patient review and were assessed by the present authors, neither of whom had been involved in the treatment of the patients (the notes were available, however). A modified Visick grading was used (Visick grade 1, symptom-free; Visick grade 2, mild symptoms and no disability; Visick grade 3, moderate symptoms involving some interference with social or economic life; Visick grade 4, recurrent ulcer or severe symptoms or the need for further surgery).

Three patients had a follow-up of less than 2 years—all in Visick grade 1,—whilst the mean follow-up on the remaining 58 patients was 7·5 years. Of these patients, 51 were Visick grade 1, 5 were Visick grade 2 and 2 were Visick grade 3. Of these 2 patients, one had occasional bouts of diarrhoea and the other patient had some indigestion which was well controlled with 'slippery elm'. The latter patient had had further barium studies which had not shown any recurrent ulceration. Both patients stated that there was an improvement on their preoperative condition.

Two patients had recurrent peptic ulceration. One lady aged 73 had had a selective vagotomy (the only one of the series) and suffered a recurrent ulcer 3 years later, adjacent to the old scar. An insulin test meal had shown incomplete vagotomy. She underwent a partial gastrectomy from which she made a good recovery.

A man aged 49 had had a duodenal ulcer as well as a lesser curve ulcer at the original operation. Six months later he had recurrent symptoms and an insulin test meal showed complete vagotomy. At reoperation an active duodenal ulcer was found. A

[illegible]ectomy was performed and he made a good recovery.

Two patients outside the series had had vagotomy, pyloroplasty and ulcerectomy, and subsequent histology showed carcinoma. One patient had had a partial gastrectomy and the specimen showed no residual tumour; he was well 2 years later. The other patient had had no further procedure and died 18 months later.

Discussion

It has been argued that vagotomy and drainage has a place in the treatment of those patients with both gastric and active (or evidence of previous) duodenal ulceration (Douglas and Duthie, 1971; Kennedy et al., 1972). Clarke et al. (1972), however, had a 10 per cent recurrence rate in this group, and they considered vagotomy and pyloroplasty a satisfactory form of treatment for high and bleeding ulcers. De Miguel (1975) has found no difference in the recurrence rates of either group, and in his long term follow-up of 71 patients undergoing selective vagotomy and pyloroplasty for benign uncomplicated gastric ulcers there was a recurrent gastric ulcer rate of 19 per cent. Postoperative X-ray studies were performed which showed that the ulcer crater healed, in most cases, in 2–3 weeks. In each of the 13 patients with recurrent ulceration the ulcer had formed at the same site as the original lesion. This is, therefore, the rationale of excising the ulcer when the vagotomy and pyloroplasty is performed.

Our results show that of 58 patients attending for long term personal follow-up, 56 have a satisfactory result (Visick grades 1 or 2) and only 2 patients out of the whole series of 90 suffered recurrent ulceration. It has not been routine to perform a postoperative arium meal unless symptoms were in any way suggestive of further ulceration. Endoscopy was not available for the majority of patients. The addition of ulcerectomy to the vagotomy and pyloroplasty procedure might well account for this low recurrence rate.

Local excision of the ulcer is a lesser procedure than partial gastrectomy, producing very little reduction in residual gastric volume; this is particularly true in the case of high gastric ulcers. In addition, in the latter situation a partial gastrectomy may be technically difficult and local excision of the ulcer may be more safely achieved.

On the basis of our figures we would suggest that vagotomy and pyloroplasty with local excision of the ulcer is a procedure worthy of wider adoption in the treatment of gastric ulceration.

Acknowledgements

We wish to thank Mr H. A. Dañiels, Mr A. W. B. Strachan and Mr J. H. Kilshaw for permission to study their patients and also Mrs J. Cornthwaite for her help in tracing the patients.

Pylorectomy and prepyloric antrectomy for gastric ulcer

JACINTO DE MIGUEL*

SUMMARY

From July 1970 to May 1977 79 patients with chronic gastric ulcer were submitted to a pylorectomy and prepyloric antrectomy (only 4–5 cm of the distal stomach being removed). In most, the excision extended in the form of a narrow tongue along the lesser curvature to include the ulcer. Vagotomy was added when signs of a healed or active duodenal ulcer were seen (19 cases). Associated lesions in the distal stomach were detected in 38 more patients.

Up to the present no recurrence has been observed and functional results have been satisfactory in 90 per cent of patients.

Preliminary results show that this operation produces a satisfactory cure for gastric ulcer, thus making more extensive resections unnecessary.

In the treatment of gastric ulcer there are two types of operative procedure in use today: excisional surgery, mainly represented by a partial gastrectomy, and conservative surgery, represented by vagotomy—truncal, selective or proximal gastric—with or without associated drainage. Of these two approaches, gastric resection has been and still is the operation most widely used.

In recent years, as a result of the writings of Dragstedt (1953), there has been repeated speculation concerning the possible influence of a hyperfunction of the gastric antrum in the formation of a gastric ulcer. Burge (1964) has emphasized the coexistence of associated pyloric lesions (pyloric hypertrophy, mucosal stenosis etc.) which, under the common denomination of 'pyloric channel disease', would contribute in a varied degree towards gastric retention. This in turn, it was suggested, would lead to an antral hyperactivity and the appearance of a gastric ulcer.

At the end of the 1960s, stimulated to some degree by personal observations of the frequent presence of distal gastric-associated lesions (de Miguel, 1970), the present author decided to test resections limited to the last few centimetres of the stomach.

Patients and methods

From July 1970 to May 1977 79 patients (68 males and 11 females) with chronic uncomplicated gastric ulcer were operated on by the author, with excision of the pylorus, about 4–5 cm of the distal stomach and the ulcer. In this operation it was accepted that some part of the antrum would be left with the gastric remnant. The ulcer crater was localized in the antrum in 21 patients, in the incisura angularis in 44 and in the lesser curve in 14. Three patients had two or more ulcers. As the ulcer was included in the resection, it meant, for most of the cases, excision of a variable extent of the lesser curvature (*Figs.* 1, 2).

In 19 cases the antropyloric excision was accompanied by a vagotomy because there were clear radiological and operative signs of past duodenal ulceration. However, the duodenal ulcer only showed itself to be active in one of these cases. The series is not consecutive because other methods were employed for the treatment of gastric ulcer over the same period. Lesions in the juxtacardial position were operated on by vagotomy and drainage for reasons of obvious difficulty and risks.

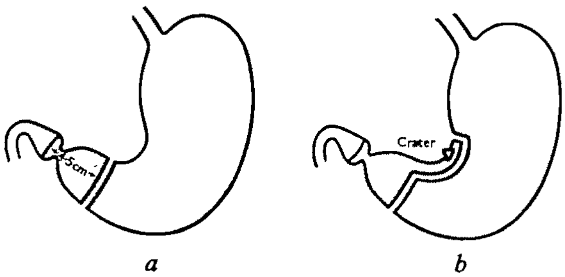

Fig. 1. Diagrammatic representation of prepyloric antrectomy (*a*) and extended to the lesser curve to include the ulcer (*b*).

Apart from the 19 duodenal ulcers mentioned above, pathological manifestations at the distal stomach were observed in another 38 patients (*Table I*). Pyloric hypertrophy was particularly common.

These different associated lesions did not always manifest themselves as duodenopyloric obstruction, although some degree of pyloric stenosis was observed in a few patients.

Follow-up studies

Twenty-five patients had their operation more than 5 years ago; in the other 45, the period of observation varied between 1 and 5 years, with an average of 2–3.

In addition to routine regular reviews, a special examination of almost all patients was carried out during the weeks before the preparation of this paper. A few patients were reviewed by postal questionnaire only. Those who complained of digestive symptoms were examined by X-rays and, when it appeared necessary, by endoscopy. One patient was lost to follow-up.

The 8 deaths during the follow-up period were due to cardiovascular diseases in 4, pneumonia in 1, accidental death in 2 and cancer of the larynx in 1.

Results

Symptoms occurring 1–8 years after the operation are summarized in *Table II*. Bile or food vomiting occurred in 3 patients, all of whom were habitual consumers of large quantities of alcohol. Fullness after meals, found in 16 patients (22 per cent), was usually slight and, in a number of cases, only presented after heavy meals. In 2 patients with associated gastric discomfort, however, fullness was constant and independent of the quantity of food consumed; X-ray and endoscopic examinations revealed the presence of large residues. Both patients were in the group having excision plus vagotomy and in both there was no pyloric obstruction. Symptoms due to milk intolerance were noticed in 23 patients (33 per cent). Early dumping, occurring approximately 30 min after meals, was seen in 12 (17 per cent) and was always mild. Four patients (6 per cent) had epigastric burning; the complaint was mild in 3 but in 1 it was the initial symptom of peptic oesophagitis which led to oesophageal stenosis necessitating surgical intervention.

Seventeen patients had increased in weight by 8–26 kg, with an average of 14 kg. Only 3 showed a

Severe		0	
Heartburn	4		5·7
Gastric or abdominal discomfort	4		5·7
Persistent loss of weight	3		4·3
Ulcer recurrence	0		0·0

Table III: SEVERITY AND TYPE OF DIARRHOEA

Type	Prepyloric antrectomy (% of 52 cases)	Vagotomy and prepyloric antrectomy (% of 18 cases)
Mild episodic	13·4	27·7
Mild continuous	0·0	5·5
Moderate episodic	0·0	5·5
Severe	0·0	0·0
Total	13·4	38·7

Table IV: OVERALL GRADING OF CLINICAL RESULTS IN 70 PATIENTS

Visick grade	No. of cases	%	
1. Excellent	47	67·1	89·9
2. Very good	16	22·8	
3. Satisfactory	6	8·6	
4. Unsatisfactory	1	1·4	

persistent loss of weight of between 6 and 8 kg, which, together with dyspeptic symptoms, caused their inclusion in the third group. The 3 led a normal working life, however, with few alimentary restrictions, and they concluded that the result of the operation was satisfactory.

Finally, none of the patients showed symptoms indicative of a possible recurrence.

Intestinal function

In this series special attention was paid to the manifestations of diarrhoea, the intensity and frequency of which are summarized in *Table III*.

After simple prepyloric antrectomy the incidence of diarrhoea was 13·4 per cent and when antrectomy was combined with vagotomy it was 38·7 per cent. It is necessary to point out that in most patients the diarrhoea was not a complaint, it was only recorded as the result of direct questioning of the patient. Relative urgency of defaecation was noted in some patients of both groups, but was more intense and frequent in those who had had a vagotomy.

Overall grading of clinical results

For this evaluation we adopted the classification of Goligher et al. (1968). Patients were placed in one of four groups according to the reviewer's estimation at the time of follow-up or questionnaire review (*Table IV*).

In group 1, as well as patients with no symptoms, there are 23 patients with milk intolerance as their only symptom and 3 others with very infrequent (three or four attacks per year), mild, episodic diarrhoea.

The most important symptoms in patients in group 2 were diarrhoea, dumping and abdominal discomfort of the mild type. In group 3 the symptoms were moderate dumping or diarrhoea, gastrointestinal discomfort and vomiting.

The only case in group 4 was a patient with peptic oesophagitis and stenosis. After a second operation with a favourable result he could be reclassified into group 3.

Discussion

Most surgical textbooks affirm the favourable results obtained in the surgical treatment of gastric ulcer by means of partial gastrectomy. However, the term 'partial gastrectomy' is ambiguous, because it can include a limited antrectomy on the one hand or a two-thirds or subtotal gastrectomy on the other. It would seem that, independent of the extent of the excision, the postoperative presentation of a recurrence is extremely rare. This implies that one might well question the need for an extensive resection. If one accepts that the appearance of adverse symptoms is in part proportional to the magnitude of the resection (Desmond, 1976), one can understand the importance of conserving the largest possible part of the gastric remnant.

If one accepts that an important cause of the pathogenesis of a gastric ulcer may lie in the hyperfunction of the antrum (Dragstedt, 1953) and that this, in turn, may be derived from or related to difficult antral emptying (Burge, 1964), it is logical to ask if the classic excision of a large part of the stomach is necessary. On the contrary, one could ask if it would be sufficient to limit the excision to the antrum itself, or even to the distal part, which is the principal site of the pathogenic lesions described by Burge (1964).

Previously published observations (de Miguel, 1970) showed that 76 per cent of patients operated on for gastric ulcer had antropyloric abnormalities leading, in many cases, to a distortion and narrowing of the pyloric canal with difficulties in gastric emptying as seen radiologically. In the present series the incidence of observed antropyloric abnormalities was similar (57, 72 per cent). It must be explained, however, why in 20 per cent of pati lesions were not observed.

Of the 79 patients included in this study, 19 had signs of scarring from a previous duodenal ulcer (only 1 showed an active ulcer). These 19 patients were submitted to a vagotomy also, with the idea of avoiding the possible risk of recurrence in the region of the gastroduodenal anastomosis. With a relatively short follow-up—only 25 patients have been followed for more than 5 years—it is not possible to assess the long term curative value of this operation, but the absence of any recurrence so far gives rise to optimism.

The assessment of the frequency and severity of diarrhoea was made after a thorough and searching interview in which even the most trivial and transient episodes of diarrhoea were noted. This may explain the incidence of 13·4 per cent after antrectomy alone. Using the same criteria, the incidence of 38·7 per cent when truncal vagotomy is included supports the view that postoperative diarrhoea is more dependent on parasympathetic denervation than on loss of the pylorus.

Other postoperative symptoms, when present, were usually very mild; for this reason clinical results were considered excellent or very good in 90 per cent of patients. One aspect which was notable at the final review was the good nutritional condition of the majority of the patients. Only the one patient suffering from postoperative oesophageal stenosis had to be considered a surgical failure (group 4). The low failure rate of 1·4 per cent after this operation must be accepted with some reservations until a longer period of observation has elapsed.

Colour lymphography in clinical surgery

D. J. LEAPER, MARY EVANS AND A. V. POLLOCK*

SUMMARY

In 38 patients undergoing femoral artery profundaplasty and in 18 having simple mastectomy with pectoral node biopsy, a 6·2 per cent solution of sodium sulphan blue was injected peripherally to outline the lymph nodes in the groin or axilla. Nodes and vessels were easily seen and the technique is now in routine use.

> Even though abundantly present, [the lymphatics] are often obscured by fat or are overlooked if not at the moment filled with fluid.
>
> RUDBECK (1653)

THE first half of the seventeenth century saw not only Harvey's discovery of the circulation of the blood but also the recognition of the nature of the lymphatic system. Gasparo Aselli first demonstrated lacteals in the mesentery of a recently fed dog in 1622 and, within a generation, lymphatic vessels had been discovered in nearly all parts of the body. During the eighteenth century William Hunter injected dyes into the lymph vessels of cadavers and was probably the first person to recognize their absorptive function (Leeds, 1977).

Since then the anatomy and physiology of the lymphatic system have been extensively investigated, but it was not until 1952 that *in vivo* lymphography was introduced by Kinmonth (1952, 1954), who pioneered both visual and X-ray lymphography using Patent Blue V and diodone, the latter subsequently being replaced by iodized poppy-seed oil (Lipiodol).

During the past 25 years, X-ray lymphography has been widely used for the investigation of lymphoedema (Kinmonth, 1972) and identification of abdominal node involvement in cancer and reticulosis (Wallace et al., 1977). It has also been used in combination with colour lymphography to outline nodes in the lower abdomen during radical hysterectomy for carcinoma of the cervix uteri, radiography being used to make sure that none was missed (Dahle, 1964; Hartgill, 1971). However, the possibility of using colour lymphography alone as an aid to the identification of lymphatic structures during operation was not realized until recently.

Vascular operations in the groin may be complicated by lymph fistulas or cysts due to unrecognized division of vessels and nodes and, at the suggestion of Mr C. V. Ruckley, we injected a blue dye peripherally to delineate these structures. Subsequently we realized that pectoral/axillary nodes could be more easily removed for biopsy if they were stained blue, and we thus adopted colour lymphography in patients undergoing mastectomy for carcinoma.

Patients and methods

The technique has been used in 38 patients undergoing femoral profundaplasty and in 18 having simple mastectomy with node biopsy. An ampoule of Disulphine Blue (Imperial Chemical Industries Ltd) is mixed with an equal quantity of 2 per cent lignocaine. For the demonstration of groin lymphatics (*Fig.* 1) 2 ml of the mixture are injected subcutaneously through a 25-gauge needle in aliquots of about 0·5 ml into the webs between the toes on the affected side (avoiding areas of gangrene). Two hours later a vertical groin incision is made and the blue lymphatics and nodes are easily avoided, ligated or sealed with surgical diathermy.

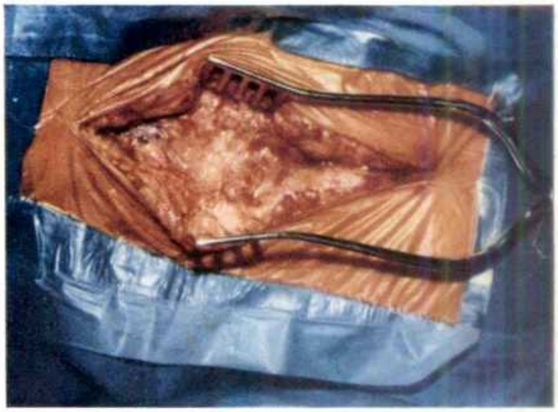

Fig. 1. Right groin dissection showing blue-coloured lymph vessels and nodes.

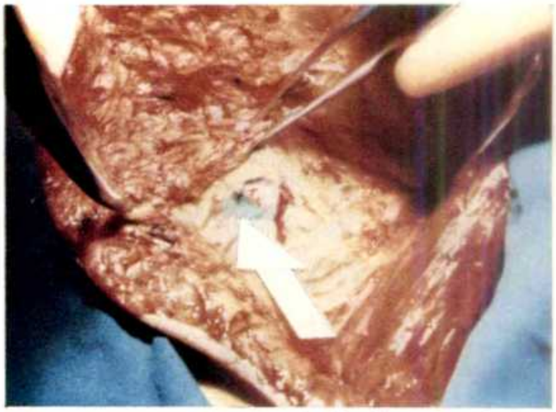

Fig. 2. Right axillary dissection showing blue-coloured nodes.

For simple mastectomy with pectoral and axillary node biopsy (*Fig.* 2), 2 ml of the same mixture are injected subcutaneously beneath the areola 2 h before operation.

Results

In the 38 patients having incisions for exposure of the upper femoral arteries, blue-coloured lymph vessels and nodes were found and no patient subsequently developed a lymph cyst or fistula. In the 18 patients undergoing mastectomy, coloured nodes were found in all but 1 (in whom the nodes were completely replaced by cancer).

Within 2 h of injection the patients' skin turned pale blue and their facies worried anaesthetists unaccustomed to the technique. The patients remained blue (and passed green urine) for a day or so and local staining of the interdigital clefts often persisted for a month or two.

---

* Scarborough Hospital, Scarborough, North Yorkshire.

Apart from the colour changes, no adverse reactions to the injections were noted and the patients reported that they were not painful.

Discussion

Nadjafi and Vollmar (1976) overcame the problem of lymph fistulas after vascular operations in the groin by placing the skin and fascial incisions well lateral to the femoral arteries and reflecting the tissues medially. If, however, the lymphatics can be seen during operation, this precaution is unnecessary.

Simple mastectomy with pectoral and axillary node biopsy is widely advocated for the treatment of carcinoma of the breast. Even in the best hands, however, nodes were not found in 17 per cent of 124 patients (Forrest et al., 1976). Turner-Warwick (1958, 1959) developed intravital techniques for the demonstration of breast and axillary lymphatics, and in the small series reported here, the fact that the nodes were stained blue was a considerable help to the surgeon.

Kett, Varga and Lukács (1970) succeeded in cannulating breast lymphatics and produced X-ray lymphograms of 88 patients. These authors found that the first node to be filled was the pectoral and from there the Lipiodol spread to a mean of 15 nodes in the axilla and supraclavicular region. Secondary carcinoma could be recognized as filling defects in the nodes, but (as in our experience) when completely replaced by cancer, they did not take up the contrast medium.

Dyes

Many dyes are absorbed from the subcutaneous tissues by the lymphatics, including Evans Blue, Direct Sky Blue and Patent Blue V (Threefoot, 1960).

Patent Blue V (Sigma) is an 11 per cent solution of the sodium salt of sulphan blue with a molecular weight of 567 and a colour index of 42045 and is widely used to identify lymph vessels in the foot before their cannulation and injection with Lipiodol for X-ray lymphography. Disulphine Blue (ICI) is a 6·2 per cent solution of the same dye and was first introduced for the assessment (after intravenous injection) of skin viability in burns (Tempest, 1960).

These dyes differ from the Patent Blue V distributed by May & Baker Ltd for Laboratoire André Guerbet, which is a 2·5 per cent solution of a calcium salt of sulphan blue with a molecular weight of 1159 and a colour index of 42051.

In the few patients (not reported here) in whom we used Patent Blue V instead of Disulphine Blue we were disappointed by the results, and in two patients the lymphatics were not coloured.

Conclusion

The use of colour lymphography is valuable in operations on the femoral artery and in those for carcinoma of the breast, and it may have applications in other branches of surgery.

The stripping of varicose veins: a clinical trial of intermittent compression dressings

D. G. MELROSE, M. T. N. KNIGHT AND E. SIMANDL*

SUMMARY

This study compares a standard method of care for patients following excision and ligation of varicose veins with a new regimen which involves intermittent compression dressings. In a fully randomized between-patient prospective trial it has been found that the use of such dressings results in a significant reduction in post-operative pain and in the length of hospitalization and indicates that such dressings may improve the healing of surgical wounds.

INTERMITTENT compression devices have been used successfully in the conservative treatment of lymphoedema whether essential, traumatic or congenital (Pflug and Melrose, 1976) and in prophylaxis against postoperative deep vein thrombosis (Hills et al., 1972; Clark et al., 1974). Initially this prophylactic action was attributed to mechanically induced changes in venous flow in the femoral and calf veins (Calnan et al., 1970). However, Allenby and colleagues (1973) showed that an action of these devices was to enhance systemic levels of circulating fibrinolytic activity following operation, and Knight and Dawson (1976) showed that, even when applied to the arms, this systemic fibrinolytic enhancement was sufficient to reduce the incidence of deep vein thrombosis in the legs despite the likelihood of venous stasis. These findings suggested a more complex action for intermittent compression, and we were interested when Pflug (1974) reported that intermittent compression had reduced pain and oedema in a number of wounds in an uncontrolled study of several surgical procedures. We have followed up this interesting observation and have set up an international, multicentre, prospective, controlled, matched series of clinical trials to evaluate this effect of intermittent compression dressings on several varieties of surgical wound. In this report we have evaluated the effect of these dressings on wounds incurred in the stripping of the long or short saphenous vein combined with multiple ligations of incompetent perforators. In particular, this matched study has assessed the degree of pain, wound oedema and haematoma formation, blood loss, the incidence of wound infection and the rate of patient rehabilitation during the postoperative period in patients with and without intermittent compression of their wounds. The results give considerable cause for optimism that intermittent compression dressings will greatly improve the healing of surgical wounds.

Materials and methods

Intermittent compression dressing

The intermittent compression dressing is cyclically inflated with air from an electric pump, which can be easily suspended from the operating table or the bed of the patient. Each pump can operate two dressings at the same time from separate output ports. The 4-min cycle is equally divided into inflation and deflation with a 15-s changeover period. The inflation is held at a plateau pressure once the required pressure is reached. The maximum pressure within the compression device is selected from a range of 20–80 mmHg by means of a simple knob and adjusted by the patient to achieve maximum pressure compatible with comfort for that individual.

All the compression dressings used in the multicentre trial have been modified from a basic tubular model to meet the requirements of the individual specialties. The basic model consists of an outer fabric coat with a more pliable inner coat that is specially laminated to allow water transpiration at the molecular level whilst remaining impermeable to air and bacteria. In this study the dressing extends from the upper thigh to beyond the toes and has an open lower end for easy visualization of the circulation of the foot. A safety valve has been fitted for rapid deflation and a zip has been fitted to increase the ease with which the dressing can be applied.

Trial design

The trial was constructed as a fully randomized between-patient prospective trial providing a considerable excess of untreated patients. This bias has allowed the statistical analysis of the results after retrospective matching of the patients based on their height, weight, age and type of operation, the presence of incompetent perforating veins or gravitational oedema or a history of previous sclerotherapy, of varicose ulceration, of recurrent superficial thrombophlebitis or of previous operations on the veins of the lower leg. No age limit was placed on patients included in the trial. Patients with diabetes mellitus, the post-phlebitic syndrome, cardiac failure, liver failure or renal failure, those with drug idiosyncrasy or those who had received radiotherapy to the operation site were excluded. Patients with very severe ulceration or oedema were excluded from the trial also.

Operative technique

The following operative technique was used and all operations were carried out by one of the authors (E.S.). The limb was prepared with 0·5 per cent Hibitane in spirit. Incisions over either the groin or the popliteal fossa and the medial or lateral malleolus were made. Proximal stripping of the vessel was arrested at the points of entry of incompetent perforators or varicose tributaries. Separate incisions were made at these points and perforators and tributaries dissected and individually ligated. At the saphenofemoral junction the long saphenous vein was flush tied at the femoral vein; the popliteal fascia was then divided and the short saphenous vein ligated at the point of junction with the popliteal vein or, if it did not join, was followed into the thigh subfascially. After the long saphenous vein had been removed, clot was expressed from the long saphenous channel using a gauze pad as a roller. 4/0 braided cotton was used for loose closure of skin wounds on the leg and in all locations. The wounds were covered with simple gauze dressings.

Control cases had 2 × 6 in crêpe bandages applied from the toes to the upper thigh and were returned to the ward with the foot elevated on two pillows. Treated patients had the compression dressing applied directly over similar dressings. On return to the ward the dressing was connected to the pump and inflation commenced at setting 2. This setting was increased by the patient to the maximum pressure consistent with comfort. Inflation was continued for 10 days for 4 h twice a day. The dressing was removed for periods of exercise, ambulation, ablution and when the patient required a short respite from treatment. Mobilization of both groups was encouraged on the first postoperative day.

Postoperative study of wounds

The assessment of the wound was scored by a given observer throughout the trial. The saturation of wound dressings was assessed daily for the first 4 days following operation and recorded on a scale: nil, 1 and 2 representing no saturation, mild or moderate saturation respectively. The presence and time of onset of a wound discharge were noted and its serous, serosanguinous or purulent nature recorded and the discharge submitted for culture. The presence of a haematoma on the fifth postoperative day was assessed and recorded on a scale: nil, 1, 2 or 3 representing the absence or the presence of a mild, moderate or severe haematoma. The degree of oedema of the leg was assessed preoperatively and on the fifth postoperative day on a scale: nil, 1, 2 or 3 representing no oedema, or mild, moderate or severe oedema.

Mobilization was divided into the following stages: walking with support, walking unaided but with a limp and normal locomotion. The time at which each stage was reached was recorded for each patient.

In this study patients remained in hospital for a fixed length of time in order to complete the study and to avoid and correct complications.

Statistical analysis

A points system has been devised to match patients with similar preoperative clinical features in order that a comparison of their postoperative course might more accurately reflect the influence of the intermittent compression dressing. The nature, findings, extent and duration of the operation and the number of incompetent perforating vessels were precisely matched for each pair. A pair was considered to be matched if the remaining dissimilarities between them did not exceed 5 points. Three points were awarded to the pair if either of the following clinical features occurred in only one member of a pair: a history of previous sclerotherapy, previous operations, previous ulceration, recurrent thrombophlebitis or the presence of an incompetent saphenofemoral junction. A single point was awarded to every 3 kg of weight difference between members of a pair and a point for every difference of 5 in. in height between members of a pair. Patients were allocated to the age groups of 25 years and below and increasing decades beyond this age. A point was awarded for each decade of difference between members of the pair. A point was awarded for a difference of one grade of oedema. A difference of more than one grade nullified the pair.

Unless otherwise stated, the statistical significance of the data derived from the matched pairs was analysed using MacNemar's test incorporating a continuity correction.

Using the above system of retrospective matching, 25 pairs out of 87 patients accumulated 5 points or less (*Table I*). No patient of a pair was included more than once. Three control patients were not included in the total of 87 because intermittent compression was used in the later postoperative period to contain postoperative oedema.

Results

Blood loss

In *Table II* the number of patients with mild or moderate dressing saturation (grade 1 ± 2) during the postoperative period is compared. On the day of the operation and on the first postoperative day there was a greater degree of dressing saturation in the treated group. There was also a significantly greater number of patients with moderate dressing saturation on the operation day and on the first postoperative day. Throughout the remainder of the postoperative period there was no significant difference in the amount of blood expressed from the wounds of the two groups.

Pain

Pain was graded nil, 1, 2, 3 or 4, classified as no spontaneous pain, slight easily tolerated pain, moderate or bothersome pain, considerable pain and agony, respectively. Pain was independently assessed by the surgeon daily, by the physiotherapist twice a day and by the patient three times a day for 7 days following operation. The total amount of pain suffered by each group, recorded by each observer and by the patient, is shown in *Table III*. This is expressed as numbers of units of pain accumulated. The treated group suffered approximately half the pain recorded for the control group and the pain lasted for a shorter period of time. This difference was highly significant ($P<0{\cdot}001$). Analgesics were confined to pethidine and aspirin and

We saved her skin

New Microporous Adhesive Ostomy Bags

Skin trouble affects a lot of stoma patients who use adhesive-held appliances. Hollister* did something about it.

We introduced a microporous adhesive *drainable* bag which has been tested in hospitals and proved outstandingly effective. The unique Hollister microporous material has thousands of tiny pores through which air can circulate, letting the skin 'breathe'. This prevents soreness caused by trapped perspiration and it's altogether more comfortable.†

Now our new microporous *closed* bag offers the same vital benefits to colostomy patients who need an adhesive held bag.

That's good news for all your ileostomy and colostomy patients who've had trouble with ordinary adhesive appliances. We can now save their skin as well.

Ceporin prophylaxis in abdominal surgery reduces primary wound sepsis

In 5 trials[1] involving 2,491 operations Ceporin was shown to significantly reduce the incidence of primary sepsis in contaminated or potentially contaminated wounds, when compared with untreated controls and with other antibacterials and antiseptics.

Resistance not a problem
Ceporin has been shown not to alter hospital ecology of bacteria. Whereas between 1971 and 1974 the number of strains resistant to ampicillin increased significantly.[2]

the amount administered during the postoperative period was recorded. Whilst there was no significant difference in the requirement for pethidine administered routinely immediately following operation, the requirement for aspirin analgesia by patients in the treated group was significantly reduced.

Oedema and haematoma formation

Table IV compares the number of patients with grades nil, 1 or 2 oedema in both groups following operation and relates them to the preoperative findings. The incidence of postoperative oedema of grades 1 and 2 in the two groups shows a significant reduction in the treated group ($P<0{\cdot}5$). No significant difference was found between the two groups with regard to haematomas, although the majority of patients in the treated group were found to have no haematoma whilst the majority of patients in the control group had some haematoma formation. No wound infection occurred in either group.

Mobilization

From *Table V* it can be seen that a significantly higher proportion of the treated patients was fully mobilized, pain-free and ready for discharge on the third postoperative day ($P<0{\cdot}5$). By the end of the third postoperative day the treated group required a total of 47 days in hospital compared with the 63 days of the control group, i.e. a saving of 41 per cent. By the tenth day after operation the treated group had required 50 days of admission whilst the control group had required 95 days, i.e. a saving of 47 per cent.

Side effects of treatment

As expected, patients differed in their reaction to the new dressing technique, but apart from mild local sweating and occasional mild discomfort there were no important side effects or contraindications.

Discussion

This study indicates that the intermittent compression dressing has certain advantages over the standard method of postoperative care used at present following excision and ligation of varicose veins. The benefits may be divided into those of economy and those relating to improved patient care.

This device resulted in a reduced intake of analgesia in the treated group with a consequent saving on the bill for drugs. More importantly, there was a 41 per cent reduction in the hospitalization time before the patients reached a state of full mobilization. This effect was not limited to patients whose postoperative course could be expected to be short. This enhancement of mobilization has two effects; first, to return patients to the comfort of their homes more quickly, and secondly, to speed up patient turnover rates with consequent saving on inpatient service costs.

Of greater importance is that the intermittent compression dressing appears to have several valuable clinical attributes. It has resulted in a highly significant halving in the postoperative pain experienced by the patients and observed by several medical observers, and further contributed to the postoperative wellbeing of the patient by causing a significant reduction in postoperative oedema of the limb and wound. This study has also shown certain trends that are not amenable to statistical analysis because the number of cases examined was too small. These trends include a reduction in the amount of clinically discernible haematoma formation in the treatment group associated with the enhancement in the expression of collections from within the wound.

This novel method of dressing wounds would appear to have fulfilled some of the theoretical precepts upon which the dressings were devised. Both intermittent compression and static crêpe bandaging markedly reduced the oedema that was detected preoperatively, but the device also produced a reduction in postoperative limb oedema which was significantly greater than that achieved by crêpe bandaging alone. We suggest that the reduction in oedema and expression of collections may have resulted in a more rapid removal of the cellular breakdown products responsible for pain and thus resulted in increased patient comfort. Also, it may be that maintaining a more normal cellular environment near the wounds has allowed more rapid mobilization and rehabilitation to take place. In this small series no patient in either group suffered a wound infection and we therefore do not have evidence to suggest that the intermittent compression dressing leads to improved cellular nutrition and hence improved cellular resistance to infection.

Most of the patients wearing intermittent compression dressings did so without complaint. Some experienced mild sweating but there were no important side effects or contraindications and the absence of these, together with statistically significant evidence that the dressing promoted more rapid recovery after surgical treatment of varicose veins, encourages us to recommend this method of postoperative treatment.

Acknowledgements

This study has been made possible by grants from the Department of Health and Social Security to Professor D. G. Melrose and to Flowtron-Aire Ltd who provided the special equipment used. We would like to acknowledge the help of Miss R. Dawson and Miss M. Clay in the analysis of the large volume of data.

Internal fixation versus primary prosthetic replacement in acute femoral neck fractures: a prospective, randomized clinical study

ODD SÖREIDE, ANDERS MÖLSTER AND TOR STEINAR RAUGSTAD*

SUMMARY

A prospective, randomized clinical study has been performed on 104 patients with an acute femoral neck fracture, comparing internal fixation (von Bahr screws) with primary prosthetic replacement (Christiansen endoprosthesis). Immediate weight bearing was allowed in both groups.

The postoperative mortality rate was similar in the two groups.

Internal fixation proved to be a less time-consuming operation, gave a shorter hospitalization time and was associated with a significantly reduced morbidity rate compared with prosthetic replacement. No blood transfusion was needed in the internal fixation group.

Primary prosthetic replacement was associated with earlier postoperative mobilization, probably gave a more definitive treatment with fewer reoperations, and showed better results at 1-year follow-up.

ACUTE, displaced femoral neck fractures are traditionally treated by reduction and internal fixation. Various fixation devices have been constructed and used in the treatment of this fracture. The failure rate following internal fixation is very high, however, and is related to the fixation device only to a small degree.

The high incidence of early and late failure which follows internal fixation has prompted many surgeons to use primary prosthetic replacement instead in the treatment of these fractures. A review of published series shows a high complication and failure rate even with this method (Hunter, 1969; Lunt, 1971; Raine, 1973). With the introduction of bone cement and more refined techniques and prostheses, however, the morbidity and failure rates have declined rapidly.

Our experience with primary prosthetic replacement has been reported previously (Söreide et al., 1975). The results were favourable and in many respects comparable with those of internal fixation, with a low morbidity and mortality rate. However, there is no general agreement concerning the place of prosthetic replacement in the treatment of acute femoral neck fractures. Indeed, many authors state that a prosthesis is not indicated in poor risk patients and many of our patients with this fracture do come into this category. Similarly, the high morbidity and mortality rate and, especially, the very high infection rate in series reported by various authors seem prohibitive.

There are only a few series in the literature comparing prosthetic replacement with internal fixation and all of them are retrospective and non-randomized (Hunter, 1969; Raine, 1973; Hunter, 1974; Johnson and Crothers, 1975). The need for a prospective randomized clinical study was obvious. Therefore we started such a trial in October 1974, a study which we hoped would solve many of the disputed problems in the treatment of femoral neck fractures in the elderly patient.

The Christiansen trunnion bearing hip prosthesis and von Bahr internal fixation screws have been used.

Patients and methods

Clinical series

Selection of patients: From 1 October 1974 all patients over the age of 67 admitted to the surgical department with an acute femoral neck fracture (Garden type 2–4) were randomized into two groups according to their date of birth. At the end of September 1976 a total of 123 patients had been admitted. One of these patients had a pathological fracture (metastasis from breast carcinoma) and 16 other patients had been systematically, incorrectly randomized (in a period when the senior author was on a study leave). These 17 patients are excluded from this study. The remaining 104 patients, 53 in the prosthetic group and 51 in the internal fixation group, form the basis for this report.

Statistical analysis: In the statistical analysis of the results, the χ^2 test and Student's t test (two-tailed) have been used.

Age and sex distribution: The age and sex distribution are given in *Fig.* 1. The mean age was 78·3 years in the prosthetic group and 77·9 years in the internal fixation group. There is no statistical difference in the age distribution of the two groups nor in the sex distribution.

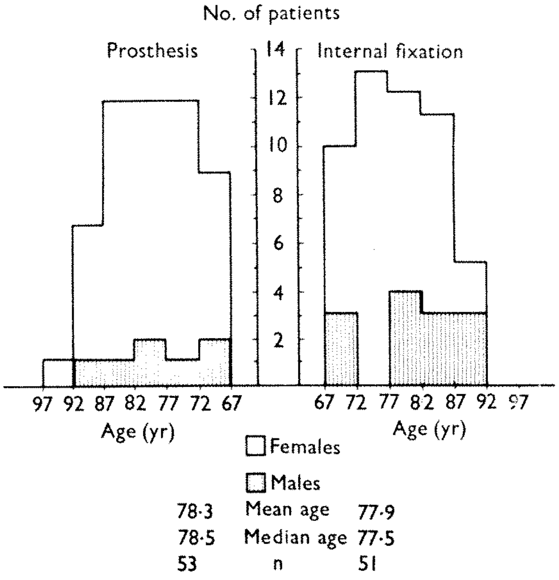

Fig. 1. Patient series: age and sex distribution.

Preoperative comparison

Great efforts were taken to evaluate the patients' preoperative general status to prevent later difficulties in interpretation of the results. The high frequency of concomitant disease found in all studies was confirmed. There was no statistical difference

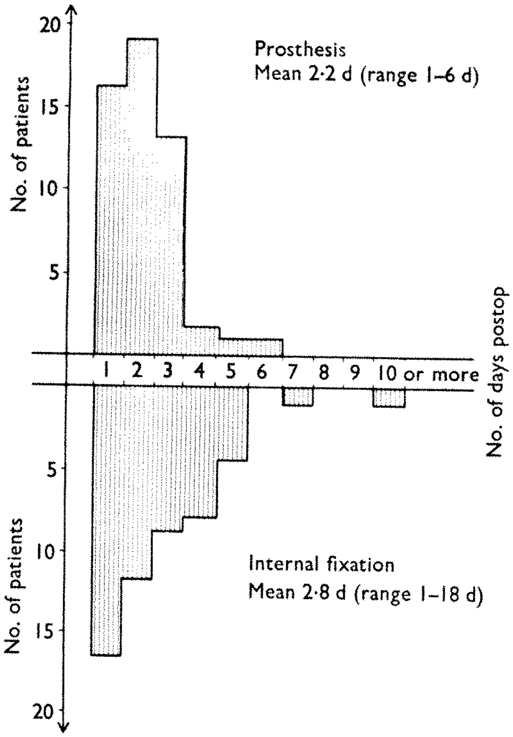

Fig. 3. Postoperative day of mobilization and weight bearing. (One patient in each group died before mobilization.)

between the internal fixation group and the prosthesis group when the frequency of concomitant disease was compared.

None of our patients was operated on as an emergency. The preoperative delay was similar in the two groups ($P > 0{\cdot}10$).

Treatment

All patients were treated by tibial traction on admission. Prophylactic anti-thrombosis therapy was started from the first day and concomitant diseases were treated if necessary. The operations were performed from 1 to 7 days later by different surgeons, as part of their surgical training.

Prosthesis group: Replacement arthroplasty was performed using a Christiansen trunnion bearing hip prosthesis. The technique has previously been described (Söreide et al., 1975). Immediate weight bearing was allowed. Penicillin and cloxacillin were administered to all patients, pre- per- and postoperatively (cephalosporins were given if penicillins were not tolerated).

Internal fixation group: The internal fixation was performed using von Bahr screws. The operative steps have been described by von Bahr et al. (1974) and Söreide et al. (1977). No antibiotics were given. Full weight bearing was started as soon as possible postoperatively.

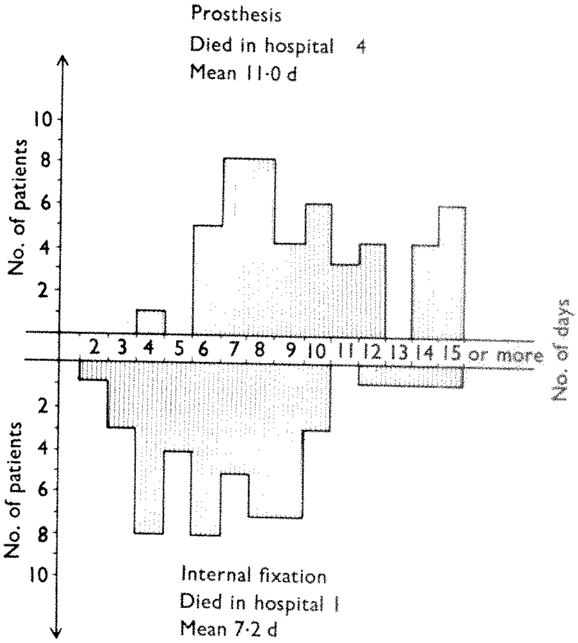

Fig. 4. Necessary time of hospitalization (for explanation *see* text).

Evaluation of the operative procedures

Duration of the operations: In the internal fixation group the mean operative time was 38 min (range 20–85 min) (*Fig.* 2). The time needed for the reduction procedure is not included. In the prosthesis group a mean operative time of 86 min was found (range 60–170 min) (*Fig.* 2). The operative time in the prosthesis group was significantly longer than in the internal fixation group ($P = 0{\cdot}005$).

Table I: WOUND COMPLICATIONS

	Prosthesis ($n = 53$)	Internal fixation ($n = 51$)
Superficial infection	3	2
Haematoma	1	3
None	48	46

The statistical difference between the groups is not significant.

Table II: GENERAL COMPLICATIONS

Complications	Prosthesis ($n = 53$)	Internal fixation ($n = 51$)
Thromboembolism	2*	0
Cardiopulmonary	3	1
Neurological	2	0
Drug exanthema	2	0
Urinary retention	3	2
None	42	48

* In one patient, more than one complication was recorded. The difference between the groups was statistically significant ($P = 0·04$).

Table III: MORTALITY RATES RECORDED POSTOPERATIVELY (FIRST MONTH), 6 MONTHS AND 1 YEAR AFTER THE OPERATION

	Prosthesis ($n = 53$)	Internal fixation ($n = 51$)
Peroperatively	0	0
First month	3 (5·7%)	3 (5·9%)
Six months	5 (9·4%)	6 (11·8%)
First year	11 (20·8%)	9 (19·6%)

The statistical difference between the groups is not significant.

Table IV: LOCAL COMPLICATIONS INDICATING FURTHER TREATMENT AT 1 YEAR AFTER THE INITIAL OPERATION

Group	Complication	No. of patients	Treatment	
			Op.	Con.
Prosthesis ($n = 53$)	Postoperative luxation	3	1	2
	Delerin luxation	2	2	—
Internal fixation ($n = 51$)	Mechanical failure	11	9	2
	Necrosis of femoral head	2	0	2

Op., Operative; Con., conservative.
Statistical difference: No. of patients, $P = 0·06$; Operative, $P = 0·06$; Conservative, n.s.

Blood loss: Blood transfusion was not needed in the internal fixation group. In the prosthesis group 18 of the 53 patients needed blood transfusion, totalling 19 000 ml (38 units) in all, which represents 358 ml per patient in the whole prosthesis group.

Mobilization and weight bearing: The first day of mobilization was recorded in both groups and is shown in *Fig.* 3. In the prosthesis group the mean time from operation to weight bearing was 2·2 days (range 1–6 days) compared with 2·8 days (range 1–18 days) in the internal fixation group. Using a one-way statistical analysis this difference is almost significant ($P = 0·06$). However, a larger series is necessary to reach a definite conclusion.

Duration of stay: Owing to the lack of long-stay geriatric hospitals, many patients stay in our hospital for a considerable time and thus the total hospitalization time is not a reliable index. We have recorded what we call the 'necessary hospitalization time', which means the time until the particular patient is walking with/without help, has no pyrexia and any post-operative complications have been treated. The necessary time of hospitalization is recorded in *Fig.* 4. The mean time for the internal fixation group was 7·2 days compared with 11 days in the prosthesis group. This difference is statistically signi[illegible] ($P = 0·01$).

Results

Early results

Morbidity: By this we mean all complications recorded in the first postoperative month which were not related to the fracture. The wound complications are listed in *Table I*. All infections in both groups were superficial and were successfully treated by antibiotics. Statistical analysis by χ^2 gave no significant difference between the groups.

The general complications experienced by our patients are shown in *Table II*. There were more complications in the prosthesis group than in the internal fixation group. This difference is statistically significant ($P = 0·04$) (χ^2 analysis).

Mortality: No patient in either group died during the operation. Mortality has been recorded 1, 6 and 12 months after the operation and the figures are shown in *Table III*. The difference in mortality rates is statistically not significant (χ^2 analysis).

Late results

The patients in the prosthesis group were followed up clinically as long as necessary. The patients in the internal fixation group were followed until healing of the fracture was complete or until failure (*see below*) had been treated. One year postoperatively all surviving patients were asked to come for a complete clinical examination and control radiograph. The mean follow-up period is 14·5 months (range 12–23 months) in the prosthesis group compared with a mean follow-up period of 14·7 months (range 12–24 months) in the internal fixation group. Thus the results obtained in each group can be compared.

Late complications: The late local complications for each group are listed in *Table IV*. In the prosthesis group postoperative luxation of the prosthesis developed in three patients. Analysis of the immediate postoperative radiographs showed that, in these patients, the prosthetic stem had been implanted in anteversion of varying degrees. Reoperation with removal of the prosthesis and implantation of a new stem in the correct position was necessary in one patient. For the other two a closed reposition procedure was performed.

The separation of the two components of the prosthetic head (here called delerin luxation), which only can occur with the Christiansen endoprosthesis,* has been reported previously from this hospital (Solhaug et al., 1976). In both our cases reoperation was necessary.

In the internal fixation group mechanical failure was found in 11 patients (22 per cent). In this context, mechanical failure means dislocation of the fracture with or without screw slippage. In 9 of these 11 patients prosthetic replacement has been performed. One patient is waiting for prosthetic replacement and in another patient reoperation is not indicated due to the patient's present general condition. Two patients presented with radiographical signs of avascular necrosis of the femoral head. No pseudarthrosis was found.

Statistical analysis (χ^2) indicated that the frequency of late complications in the internal fixation group

---

* The design of the Christiansen endoprosthesis has now been changed in order to avoid this complication.

[illegible] probably higher than in the prosthesis group [illegible] = 0·06). Similarly, the need for a second operation was probably greater in the internal fixation group than in the prosthesis group ($P = 0{\cdot}06$).

Late infection: In one patient belonging to the prosthesis group deep infection occurred and the prosthesis had to be removed. We feel, however, that this case is not typical of the infection that is relevant in this discussion, which we hope to clarify with the patient's history.

Case report: An 89-year-old female patient in a mental hospital was admitted in June 1976 with an acute femoral neck fracture after a fall. According to randomization she received primary prosthetic replacement. There were no postoperative complications, particularly no infection.

After discharge she developed a flexion contracture in the operated hip and, in August 1976, bedsores over the trochanteric region. The prosthesis then luxated and soon became visible. Infection supervened and the prosthesis had to be removed.

For the purposes of this study, this patient has been classified as a failure.

Follow-up examination: Of the surviving patients, 5 in the prosthesis group and 2 in the internal fixation group were not examined because they had moved away from the area. Thus 36 patients in the prosthesis group and 31 patients in the internal fixation group were available for follow-up examination.

The ability to walk and the need for walking aids are recorded in *Table V*. There is no significant difference between the groups (analysis by χ^2).

Objective hip assessment was performed using Stinchfield's classification system (*Table VI*) and the results are given in *Table VII*. The 11 patients in the internal fixation group with primary mechanical failure have all been classified as poor. In the prosthesis group the patient with deep infection and one patient with an unsuccessfully repositioned dislocated prosthesis have also been recorded as poor. In the prosthesis group 30 out of 38 patients obtained the classification excellent or good, compared with 23 of the 42 patients in the internal fixation group.

When comparing the number of patients in each group classified as excellent or good with the number of patients in the two groups classified as fair and poor the results in the prosthesis group are significantly (χ^2) better than in the internal fixation group ($P = 0{\cdot}025$).

Range of movements in the operated hips: Two patients in the prosthesis group had a flexion contracture of 5° compared with 3 patients in the internal fixation group with contractures of 10°, 15° and 25° respectively. The range of movements in all the patients that were examined is shown in *Fig.* 5 (left hip turned). Statistical analysis revealed no difference between the groups.

Discussion

As shown in this paper, primary prosthetic replacement does not lead to increased postoperative mortality compared with internal fixation. This finding contrasts with the general view recently expressed by Garden (1977) and the findings in non-randomized groups of patients (Hunter, 1969; Lunt, 1971; Hunter 1974). The low mortality rate in the prosthetic group, however, is in good accordance with the results of a previous study of primary prosthetic replacement from this hospital (Söreide et al., 1975).

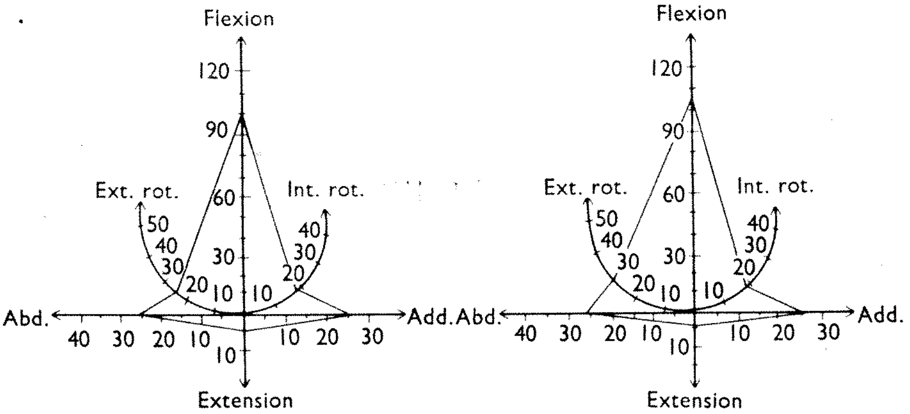
Poor	3	12

The difference between the groups was statistically significant ($P = 0{\cdot}025$).

Primary prosthetic replacement, on the other hand, is followed by an increased morbidity rate compared with internal fixation. This finding corresponds well with those of other authors (Hunter, 1969; Raine, 1973; Hunter, 1974; Johnson and Crothers, 1975). This increase must reflect the difference in the magnitude of the two operative procedures, reflected in the increased operation time and the greater blood loss in the prosthetic group. Interestingly, the increased



Prosthesis

Internal fixation

Fig. 5. Range of movements in the operated hips according to Spangfort's scheme (left hip turned).

morbidity rate did not result in an increased mortality rate.

Both operations carry the risk of complications requiring secondary treatment. The reoperations in the prosthetic group follow luxation or loosening of the prosthetic stem, protrusion into the acetabulum or deep infection. Postoperative luxation can be avoided by careful peroperative technique as previously shown (Söreide et al., 1975). Protrusio acetabuli has not been a problem with the Christiansen endoprosthesis (Kavlie and Sundal, 1974; Söreide et al., 1975). The only serious threat to a good functional result is deep infection. Although the infection rate in this study can be said to be zero, previous experience (Söreide et al., 1975) and a literature survey clearly show that postoperative infection cannot be totally avoided. In the internal fixation group reoperations are needed owing to mechanical failure, non-union or necrosis of the femoral head. The frequency of these complications has been remarkably constant during the years (Öhman et al., 1969; Johnson and Crothers, 1975; Tillberg, 1976). Garden (1971, 1977) and Barnes et al. (1976) have presented convincing data showing that the complication rates can be reduced by better operative technique. This is in accordance with our findings (Söreide et al., 1979). From this study, however, it appears that primary prosthetic replacement offers the most definitive treatment.

We have shown that the results of 1-year follow-up examination are better in the prosthetic group than in the internal fixation group. However, the results of endoprosthetic replacement and of internal fixation *plus* later prosthetic replacement in the patients with mechanical failure, non-union on necrosis of the femoral head would probably be identical. However, the 'two-step' approach to the treatment of femoral neck fractures in the elderly puts a greater burden on the hospital's services and finances, and reoperations represent another threat to the life of these patients. The cost-effectiveness problem must also be considered when comparing these two types of treatment.

Acknowledgements

We would like to thank the former head of the Department of Traumatology and Orthopaedics, Professor Sven Olerud, whose inspiration and enthusiasm inspired this study. The statistical analysis was performed by Statistician Siri Nome Ekhom, of the Medical Faculty, University of Bergen.

A 'universal' tube-holding device

LAURENCE F. TINCKLER*

DURING medical and surgical practice there are many and varied occasions on which it is necessary to retain tubes in the patient for diagnostic and treatment purposes. The traditional way of doing so is to use an anchoring suture in the skin, strapping and bandaging. Either as an alternative or as a complement to these methods of retaining tubes, a device has been made available which is both convenient and effective and enables tube positions to be easily adjusted if required.

The device is made of plastic and is disposable. It consists of a base plate on which are mounted two flanges in parallel. The flanges bear a series of slots tailored to receive a variety of tubes, such as those used for infusion, transfusion, catheterization and drainage (*Fig.* 1).

In use, the device, supplied presterilized by ethylene oxide in a double-wrapped package, is stuck to the patient's skin by means of a double-sided plaster on the base plate. The tube to be retained is inserted into the flange slots of appropriate size so that it is gripped firmly, without obliterating its lumen, at two sites in a cleat action.

The purposes for which the 'universal' tube-retaining device can be used are intravenous infusion and transfusion; wound drainage by vacuum drains, suction sump drains and passive tube drains; common bile duct T tube drainage (*Fig.* 2); fistula suction (*Fig.* 3); ureteric catheterization for retrograde pyelography; cardiac and Seldinger arterial catheterization.

The device is available from Downs Surgical Ltd, Church Path, Mitcham, Surrey.

Paper accepted 7 July 1978.

Splenectomy for undiagnosed splenomegaly

A. GOONEWARDENE, J. B. BOURKE, R. FERGUSON AND P. J. TOGHILL*

SUMMARY

During the 9-year period 1968–76 116 splenectomies were performed at the General Hospital, Nottingham. Of these, 13 (11 per cent) were undertaken for unexplained splenomegaly. In 6 patients a diagnosis was established by the operative procedure (2 with sarcoidosis, 2 splenic cysts, 1 Gaucher's disease and 1 haemangiosarcoma). Histological examination of the excised spleens in the remaining 7 patients showed no specific features. Two of these patients benefited considerably from removal of very large spleens. Another patient died from lymphosarcoma which was diagnosed 21 months after splenectomy. In the remaining 4 patients with mild to moderate splenomegaly, there were no real diagnostic or therapeutic advantages. It is concluded that splenectomy should always be considered in patients with unexplained moderate or gross splenomegaly but it may not be helpful in the patient whose spleen is only mildly enlarged.

IN most patients living in temperate climates, the cause of an enlarged spleen is readily determined by clinical investigation. Even after careful evaluation, however, a small group of patients remains in which the cause of the splenomegaly is uncertain. Some of these patients appear to be in robust health whilst others are obviously ill. When non-invasive techniques have failed to reveal the cause of the splenic enlargement, splenectomy has to be considered.

Under these circumstances, the primary objective of splenectomy is positive pathological diagnosis. Additionally, there may be other secondary benefits, such as the cure of a hypersplenic state, the reduction of an expanded plasma volume or the removal of a large tumour which has become a painful and cumbersome burden. These advantages have to be set against the appreciable morbidity and mortality of splenectomy and the long term vulnerability to infection of the asplenic state (Ramsay and Bouskill, 1973). Unfortunately, there is the possibility that the excised splenic tissue may have no specific histological characteristics, leaving the clinician uncertain as to whether he is dealing with a benign disorder or a more sinister process, presaging a lymphomatous or leukaematous state.

The potentials of diagnostic splenectomy have been discussed in standard texts but there have been few detailed reports in recent years. Herman and his colleagues (1968) described 52 patients who underwent splenectomy for unexplained splenomegaly at the Cleveland Clinic during the preceding 10 years. Of these patients, more than half were found to be suffering from lymphoma or congestive splenomegaly and in only 1 case was the diagnosis still uncertain after splenectomy. Although other authors have reported groups of patients with specific diseases that were diagnosed at splenectomy (Hickling, 1964; DasGupta et al., 1965; Skarin et al., 1971), there have been no recent descriptions of the results of splenectomy for undiagnosed splenomegaly after full conventional investigations. This paper describes 13 such patients.

Patients and methods

The 13 patients whose clinical data are summarized in *Table I* formed part of a series of 116 splenectomies carried out at the General Hospital, Nottingham, during the period 1968–76. Of the 116 splenectomies, there were 21 associated with major upper abdominal surgery, 32 for traumatic or spontaneous rupture of the spleen, 17 for idiopathic thrombocytopenic purpura, 12 for various forms of haemolytic anaemia, 13 for lymphoma, 5 for chronic leukaemia and 3 for myelosclerosis. The remaining 13 cases were undiagnosed before splenectomy and are reported in this paper.

Each of the patients subjected to splenectomy for undiagnosed splenomegaly had had repeated peripheral blood film examinations and bone-marrow and/or trephine biopsies.

Blood from all patients was assessed for haemolysis by routine haematological methods. Measurements of red cell mass (RCM), splenic red cell pool (SRCP), red cell survival (RCS) and surface counting studies were also carried out in *Cases* 3, 4, 7, 8, 9 and 11, using ^{51}Cr-labelled erythrocytes as described earlier (Toghill and Green, 1975). Plasma volumes (PV) were measured using ^{125}I- or ^{131}I-labelled human albumin. The results of these investigations are shown in *Table II*. In only one patient (*Case* 11) was there evidence of frank haemolysis with excessive splenic uptake on surface counting. This patient's red cell survival (T_{50} ^{51}Cr) was reduced to 10 days (normal 24–28) and the splenic sequestration index increased to 250. This index was calculated as described by Parker et al. (1977), a value of greater than 100 indicating moderate to severe red cell destruction in the spleen (Jandl et al., 1956).

All patients had routine liver function tests performed and all had liver biopsies except *Cases* 8, 10 and 11, in whom this procedure was contraindicated by a haemorrhagic tendency. Liver and spleen scans were performed in all patients using ^{99}Tc^{m} with routine anterior, posterior and lateral views. Evidence of oesophageal varices was sought by endoscopy or radiology. None of the patients had clinical lymphadenopathy and diagnostic scalene or other lymph node biopsy was not performed before the laparotomy for splenectomy. Eight of the 13 patients had lymphangiograms, but these were all interpreted as being normal. Diagnostic splenic aspiration was not utilized. At laparotomy for splenectomy several lymph nodes were taken for biopsy purposes from the root of the mesentery and the para-aortic regions.

Findings after splenectomy

The results of diagnostic splenectomy are shown in *Table I*. There was no immediate operative mortality, although one patient (*Case* 8) died 5 weeks after her operation without leaving hospital.

Patients with positive findings at splenectomy

A definite histological diagnosis was achieved in 6 of the 13 patients. Two patients (*Cases* 2 and 3) who came to medical attention because of pain in the left upper quadrant were shown to have congenital splenic cysts. The diagnosis had been suggested by patchy uptake on the spleen scans. A youngster of 16 (*Case* 6) had been found to have an enlarged spleen at routine school medical examination and splenectomy revealed the diagnosis of Gaucher's disease. No other members of the family were affected and there were no other physical stigmas of the disease. Bone-marrow biopsy and trephine and liver biopsy had been unhelpful. An elderly man (*Case* 10), previously reported (Toghill et al., 1972), was shown to have haemangiosarcoma. Rupture of the spleen precipitated emergency surgery a few hours before splenectomy had been planned. *Case* 1

(a) Findings before splenectomy; (b) findings at last follow-up.

was admitted to hospital as an emergency with a pneumothorax and was found to have an enormously enlarged spleen. Diagnostic splenectomy revealed sarcoidosis, which had seemed unlikely on clinical grounds in view of the massive splenomegaly. *Case* 12, who presented with pruritus, was confidently expected to have a lymphoma, but histological examination of both spleen and abdominal nodes showed sarcoidosis.

Patients with non-specific histology

There were no specific diagnostic features at splenectomy in the other 7 cases. In one patient (*Case* 11), the splenomegaly preceded the development of overt lymphosarcoma by almost 2 years. This patient had been investigated extensively preoperatively for a Coombs negative haemolytic anaemia, leucopenia and thrombocytopenia. Surface counting using ^{51}Cr-labelled erythrocytes showed excess splenic uptake. Splenectomy resulted in a gratifying haematological improvement for 21 months until the patient showed clinical evidence of lymphosarcoma which caused her death 3 months later.

Two patients (*Cases* 4 and 9) had massive spleens that were associated with some features of hypersplenism. Neither of these patients had evidence of excessive splenic uptake on surface counting but each had large splenic red cell pools of 13 and 28 per cent of the RCM respectively. In addition, the plasma volume in each case was increased above the normal value of 34–48 ml/kg. Much of the initial haematological improvement after splenectomy in these patients was likely to have been due to the removal of the large SRCP and reduction of the expanded plasma volume. Both patients have now lived for 2 and 8 years respectively in excellent health.

In 4 other patients with mild to moderately enlarged spleens weighing from 245 to 800 g splenectomy failed either to achieve a diagnosis or to improve the health of the patients, although in *Case* 13 there was a satisfactory rise in the platelet count from a worryingly low level of 30 × 10⁹/l to 87 × 10⁹/l. *Case* 8 had been investigated extensively preoperatively for mild splenomegaly, a normochromic anaemia and thrombocytopenia. This patient died 5 weeks after splenectomy from continuing thrombocytopenia and subsequent autopsy failed to reveal a specific disease process. *Cases* 5 and 7 have now been followed up for 2½ and 3 years respectively and neither has developed any new or diagnostic features.

Table II: RESULTS OF HAEMATOLOGICAL INVESTIGATIONS

Case	RCM (ml/kg)	SRCP (% of RCM)	RCS (T_{50} ^{51}Cr)	Surface counting studies	PV (ml/kg)
3	24·0	0	24 d	No excess splenic uptake	38
4	26·5	13	22 d	No excess splenic uptake	50
7	19·7	18	18 d	No excess splenic uptake	NE
8	16·2	5·5	14·5 d	No excess splenic uptake	NE
9	13·8	28	22 d	No excess splenic uptake	60
11	23·7	6	10 d	Excess splenic uptake (splenic index + 250)	NE

RCM, Red cell mass (normal 25–36 ml/kg); SRCP, splenic red cell pool; RCS, red cell survival (normal 24–28 d); PV, plasma volume (normal 34–48 ml/kg); NE, not estimated.

Table III: DIAGNOSTIC VALUE OF SPLENECTOMY IN SOME REPRESENTATIVE WORLD SERIES

Period	No. of cases	Type of material	No. in whom diagnosis uncertain at splenectomy	Diagnostic splenectomies (%)

Discussion

Many of the larger series of splenectomies reported in the past 10 years have included a proportion of patients in whom the diagnosis was uncertain at the time of splenectomy. *Table III* includes some representative series from various parts of the world, indicating that up to 12·5 per cent of patients who undergo splenectomy are undiagnosed at the time of operation. In the largest group, Herman and his colleagues (1968) considered that 52 of their 582 patients had had splenectomies primarily for diagnostic purposes. With the more liberal use of liver biopsy, lymphangiography and organ scanning by ultrasound or computerized axial tomography, however, it is likely that fewer cases in the future will need to proceed to splenectomy for diagnosis.

Many authors have pointed to the value of splenectomy in the initial diagnosis of lymphoma (Hyatt et al., 1970; Schwartz et al., 1970; Skarin et al., 1971; Long and Aisenberg, 1974; Case Records of the Massachusetts General Hospital, 1976). Herman and colleagues (1968) found 31 per cent of their cases of diagnostic splenectomy to have lymphoma. However, the wide spectrum of diseases that may be delineated by diagnostic splenectomy includes sarcoidosis (Herman et al., 1968), splenic cysts and abscesses (Herman et al., 1968; Chulay and Lankerani, 1976), primary tumours of the spleen (DasGupta et al., 1965), splenic angioma (Rhochmis, 1970) and splenoma (Bhagwat et al., 1975).

In our 5 patients in whom an accurate histological diagnosis was achieved it was gratifying to be able to assure *Cases* 2 and 3 that they had benign disorders. Previously both had undergone extensive investigation and they had been given a guarded prognosis. It was thought that *Cases* 1 and 6 might be suffering [illegible] lymphoma, though splenectomy showed sarcoidosis and Gaucher's disease respectively, diseases with a somewhat better prognosis. Nevertheless, it must be remembered that splenectomy in Gaucher's disease, though proving the diagnosis, may possibly result in an extension of the osseous and hepatic lesions (Matoth and Fried, 1965) and may also render the child vulnerable to the fulminating infections known to occur in the asplenic state (Ramsay and Bouskill, 1973).

Our own series is characterized by the high proportion of cases (7 out of 13) in which the splenic histology was non-specific, though we realize that some of these cases may eventually proceed to frank lymphoma, as did *Case* 11. Undoubtedly enlargement of the spleen may be a foreboding of subsequent lymphoma, and information derived from diagnostic laparotomy and staging splenectomy in Hodgkin's disease indicates that considerably enlarged spleens may be free from disease (Glatstein et al., 1970; Ell et al., 1975). We believe that two of the patients (*Cases* 4 and 9) are probably examples of the syndrome previously described as idiopathic, non-tropical splenomegaly (Dacie et al., 1969) or primary splenic hyperplasia (Weinstein, 1964). In these syndromes, the spleen may be grossly enlarged without there being consistent or significant histological changes. Splenectomy produces a clinical and haematological improvement without serious disease necessarily developing. Both *Cases* 4 and 9 derived relief from the removal of large uncomfortable spleens, and from the effects of the 'big spleen' syndrome, including pooling of erythrocytes and platelets in the spleen and expansion of the plasma volume. Splenectomy failed to establish a diagnosis in the 4 other patients (*Cases* 5, 7, 8 and 13), and as these patients had only mildly enlarged spleens; there were no other benefits. Certainly their spleens were significantly enlarged (DeLand, 1970; Myers and Segal, 1974) and, in association with obvious haematological abnormalities, there was some basis for diagnostic splenectomy.

Our conclusions are that in some cases splenectomy for unexplained splenomegaly may be a useful diagnostic procedure. When splenomegaly is only mild and there is no evidence of disease elsewhere, the indications for diagnostic splenectomy are arguable. Routine examinations of college freshmen have shown 1 per cent with palpable spleens for which no sinister cause was found after a 6-year follow-up (McIntyre and Ebaugh, 1967). There have also been suggestions that splenic infarction might be responsible for some cases of mild to moderate splenomegaly in otherwise healthy folk, and although results of angiography and scanning may be abnormal, the gross changes may be non-specific (Russell et al., 1976). With the larger spleens the diagnostic yield after splenectomy is likely to be greater, but it must be admitted that even with modern techniques some of the large spleens will be undiagnosed after splenectomy. Nevertheless, in patients with the 'big spleen' syndrome, other benefits may accrue simply from the removal of the very large organ.

Erratum

The publishers regret that in the November 1978 issue of the *British Journal of Surgery*, in the article by George A. Khoury et al., 'Tuberculosis of the peritoneal cavity', on pp. 808 and 809 *Figs.* 1 and 3 were transposed.

It has also been brought to our attention that the article by L. E. Hughes and J. F. Forbes 'Early breast cancer', *Fig.* 2 on p. 760 is incorrectly labelled: *c* should read *a* and vice versa. Also, on p. 768 the reference to *Table III* should read *Table II*.

Br. J. Surg. Vol. [illegible] (1979) 66

A hazard of the Eder–Puestow system for oesophageal dilatation

JOHN BANCEWICZ*

THE introduction of the Eder–Puestow system (Puestow, 1955) for oesophageal dilatation, in conjunction with fibreoptic instruments, has been a significant advance (Price et al., 1974). By this technique the stricture is visualized with a flexible fibreoptic oesophagoscope and a guide wire is passed through the stricture via the biopsy channel of the instrument. The oesophagoscope is then withdrawn and dilatation is achieved by passing graded metal bougies over the wire. These bougies have a flexible guide spring at the tip and the shaft is also flexible. The use of entirely flexible instruments probably reduces the risk of oesophageal perforation. In addition, dilatation can frequently be carried out under topical anaesthesia and diazepam sedation. As this system is relatively new, however, it is too early to say whether it is associated with any particular complications of its own. This report describes a complication that occurred during the use of Eder–Puestow dilators and which has not been reported before.

Case report

A 35-year-old woman underwent bouginage of a fibrous stricture in the upper third of the oesophagus which developed after oesophageal resection for carcinoma. This was carried out under general anaesthesia at the patient's request. When one of the larger bougies was withdrawn it was seen that the flexible guide spring had broken off the end of the bougie. This spring is prevented from slipping off the end of the guide wire by an expanded 'fingertip' on the guide wire which guards against oesophageal perforation. An attempt was therefore made to withdraw the spring by simply pulling out the guide wire. Unfortunately this could not be done as the spring appeared to stick at the site of the oesophageal stricture. It was necessary to pass a small, rigid oesophagoscope over the guide wire down to, and almost through, the stricture. Once this had been done, the guide wire and guide spring were removed quite easily.

The reason the guide wire could not be withdrawn is clear from *Fig*. 1. As can be seen, the guide spring had broken off the metal ferrule which is screwed into the rest of the bougie. A sharp spike of spring remained and had become stuck in the stricture. This might have caused marked damage had any force been used to withdraw the guide wire.

It is the author's belief that this untoward event has not been reported before. Our dilators have now been in use for about 2½ years and, as can be seen from *Fig*. 2, the guide spring tends to become distorted with time. This probably results from repeated screwing and unscrewing of the spring and the coils on the metal ferrule become stretched. Users of the bougie system should be aware of this and guide springs that become distorted in this manner should be discarded before breakage occurs. It is planned to include an appropriate warning in the instructions for the use of the bougies (Messrs KeyMed, personal communication).

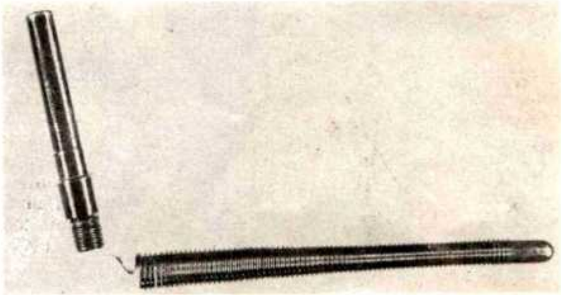

Fig. 1. The broken guide spring.

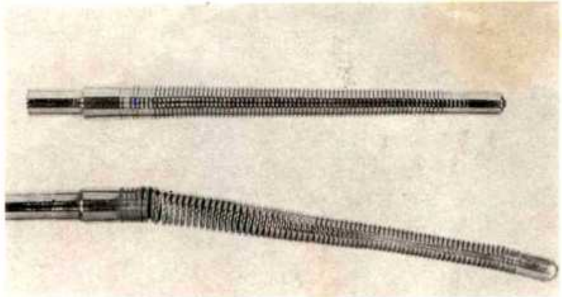

Fig. 2. New and used guide springs, showing the distortion that can occur with time.

respondence

Trasylol in primary acute pancreatitis

Sir,

It is always difficult to draw direct comparisons between laboratory and clinical studies. The tests of antitryptic activity of Trasylol in the dog described by Dr Miller (*Br. J. Surg.* **65**, 887) do not bear great resemblance to canine models of experimental acute pancreatitis as the large doses of trypsin used, even in the fourth group of dogs given supplementary Trasylol 10 min later, resulted in death in less than 50 min. Even the more severe forms of canine experimental pancreatitis without Trasylol therapy usually require from 6 to 24 h to result in the death of the animal. Nevertheless, the results presented of the interactions of intravenous trypsin and intravenous Trasylol are in broad agreement with earlier studies (Grozinger, 1966) that the larger the dose of Trasylol and the smaller the time interval from insult, the more effective the drug's antiproteolytic activity.

With respect to the tests of the duration of existence of Trasylol in the blood, Dr Miller found only limited inhibition of trypsin using BAPA as a substrate. These results must be viewed in the light of our knowledge that even when trypsin is complexed with alpha-macroglobulin or alpha$_1$-antitrypsin these complexes still retain trypsin-like activity in terms of splitting this substrate (Ohlsson, 1971; Ohlsson and Tegner, 1973). It is, therefore, possible that complexes of Trasylol and trypsin also retain trypsin-like activity and an ability to split BAPA. Our own laboratory work, which will be published in detail shortly, has shown that very high dosage intravenous Trasylol therapy (20 000 KIU/kg) in the dog is totally effective in preventing death administered up to 6 h after induction of acute pancreatitis (Imrie and Mackenzie, 1977). In terms of clinical acute pancreatitis, both our study (Imrie et al., 1978) and that of the Medical Research Council (MRC Multicentre Trial, 1977) have demonstrated that there is no value in giving a starter dose of 500 000 KIU of Trasylol intravenously followed by a further 4–5 million units over the next 5 days to patients with acute pancreatitis. We are presently assessing in the clinical context a much higher dose of intravenous Trasylol given for a much shorter time, but in the present state of knowledge, Trasylol should be withheld in the treatment of primary acute pancreatitis.

Book reviews

Achalasia of the Cardia

H. R. S. Harley. 215 × 135 mm. Pp. 174, with 83 illustrations. 1978. Bristol: Wright. £10·00.

THIS monograph on a not particularly common condition can be divided into two parts. The first three chapters are concerned with theoretical considerations and the latter part of the book goes into the clinical manifestation. The theoretical considerations are divided into morbid anatomy and histology, motility and aetiology. Much of the morbid anatomy is not yet fully understood and it is doubtful if it is necessary to carry out motility studies to establish the diagnosis of achalasia. Little is known for sure about the aetiology. Added to all this the text of these sections is so interspersed with references, or perhaps the references in places are interspersed with text, as to be almost unreadable. If there is to be another edition, then it is suggested that another system of references should be adopted.

When the author comes to describe the clinical aspects he is clearly much more at home and he gives a lucid account of the symptomatology based on his own experience and he very properly stresses the frequency of pain as a symptom of a condition usually thought to cause only dysphagia. As far as treatment is concerned the author is a strong advocate of a transthoracic Heller's operation and there is an interesting discussion on the optimum extent of the incision in the oesophageal muscles.

It is a pity that the many X-ray illustrations are poorly reproduced and so small, but this, presumably, is in the interests of economy.

J. W. P. GUMMER

The Care of Congenital Hand Anomalies

Adrian E. Flatt. 245 × 168 mm. Pp. 371 + viii, with 745 illustrations. 1977. St Louis: Mosby. £27·20.

THIS book is, as the author says, 'a personal report to describe one man's surgical approach and philosophy in care and dealing with these problems'. This is a good start because so often nowadays a book of this sort relies for its content upon numerous authors who, in spite of careful editing, inevitably overlap and whose style of writing inevitably differs.

The role of reconstructive surgery in congenital hand deformities is carefully considered having due regard for the parents and relatives and indeed for the child. It is not often that surgery can make a hand look normal, but quite frequently the functional capacity can be increased considerably. In childhood, as the author points out, congenital deformities are far more of an embarrassment to the parents than to the patient and the surgeon has to be very wary lest he fall into the trap of treating the parents rather than the child.

This is a very down to earth account of the commoner deformities that can affect the hand and fingers and the ways in which the disabilities can be ameliorated. The diagrams and illustrations are superb and are carefully chosen to illustrate and enlarge the text. There is a very comprehensive bibliography and an equally useful glossary. The whole work is rounded off by a unique 'syndromes' index.

I found this a delightful book and Adrian Flatt's easy style of writing is a pleasure to read. The production is excellent and selling in this country at £27·20 this is good value.

DONAL BROOKS

Instructional Course Lectures: The American Acad Orthopaedic Surgeons.

Chairman: H. A. W ssinger. 278×214 mm. Pp 227 with 236 illustrations. 1977. St Louis: Mosby. £22·00.

The intention of this book as stated in the brief preface is to select subjects which are important to the orthopaedic sur yet might not appear elsewhere in more conventional litera-ture. This aim is certainly achieved and most of the chapters deal with their subject in a comprehensive manner.

The first section on orthopaedic sepsis reviews both infec-tions of bone and joint and presents attitudes towards h prevention of surgical sepsis, the latter being a subject discussed in recent years. However, it was in th section on hand surgery that I found the greatest Excellent comprehensive chapters on the subjects of plexus lesions, skin coverage the injured h struction of the spastic upper to read and of equal value as paedic specialists as they are ist ing. In section three th subjec is discussed in an equ y int

ID PATON

Diseases of the Gall Bladder and Biliary System

Edited Leslie J. Schoenfield. 253×175 mm. Pp. 362+xiii. 1977. Chichester: Wiley. £21·75.

This is a well-written text, but it is probably for library consulta-tion rather than personal ownership. The most important contribution is on the topic of gallstones with an excellent discussion of the current status of medical treatment which, quite appropriately, occupies about half the text. The remainder of the book is an up-to-date review of our current knowledge of the less common disorders of the biliary tract. The figures and tables are well selected, and the radiograph reproductions of good quality.

There have been so many books on this and related topics in the past few years that it is difficult to assess this monograph in perspective. For a surgeon who professes a special interest in biliary problems, this is a very appropriate reference. It is engagingly written in a personal way which makes it easy to read and it contains most of the important references.

C. G. CLARK

Butterworths' Medical Dictionary

Edited Macdonald Critchley. Second edition. 285×225 mm. Pp. 1942. 1978. London: Butterworths. £45·00.

Beginning in fine form with a preface that alludes to such varied literary giants as Dr Johnson, Dylan Thomas, Sir William Gowers and Voltaire, the editor straightway warns us that he is one who still embraces archaicisms, not because they still might be needed, like old junk in a spare room cupboard, but from the fact that life is, from time to time, breathed into the dead bones of such memorabilia during their routing out by students of today, as long as they have the means to understand what they find. As one who remembers an instance of much distress and a near fatality that followed upon the use of the word 'singultus' in a crucial context in GP's letter instead of the more widely understood 'hiccup', feel that there are two ways of looking at such latter day sil-hunting. Yet it is right that we should be reminded Philistines we doctors are when it comes to the writing air prose. We really cannot hear too often the wise advice Richard Asher, Charles Thorne or Hugh Dudley, yet ost of us go on writing gobbledygook, quite unaware of remedial advice that is close to hand for anyone who eps Fowler on his study shelf.

How about eponym ably and very properly, keeps them in concern for the origins of medical knowledg shown in the elegant use of proper names that wise be forgotten, even though in the Unite example, Crohn's disease has become regional an imperfect description and nowhere near a same can be said when thromboangiitis obl a s trasted with the far more acceptable Buerger's disease.

The name w contributors form a most exclu e list are many of the ot just experts, though they numental volume. It includes f all known fistulas (with correct mammary from another that is id impartial entry on the National ation Act (1973) and a dozen closely aments of man. What a help such a who needs accurate and reliable guidance ing himself to unforgiving print.

cism, on a matter that no doubt was decided m the outset, concerns the almost total lack of detail in the numerous entries under the names of distinction and importance, or the lesser person who would be useful to know something more than the year of their birth, their work and where they lived. Still, their contributions are listed, defined, and I suspect, complete.

The new *Butterworths' Medical Dictionary* is a must for our libraries, and most medical writers would be helped by owning one. At £45, by the values of today, it is cheap at the price and at the same time a treasure to possess.

H. H. G. EASTCOTT

Current Practice in Orthopaedic Surgery

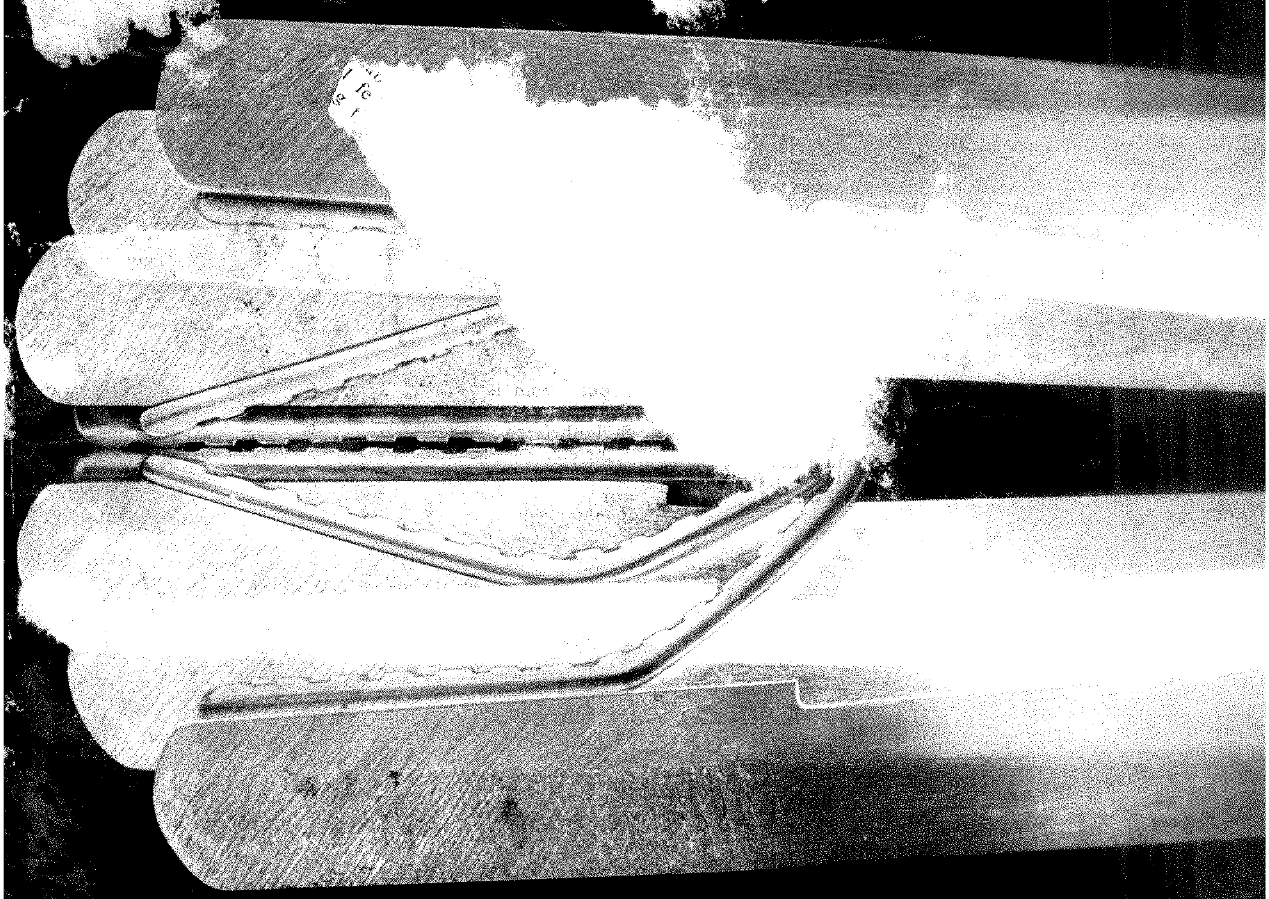
Edited Ahstrom. 246×170 mm. Pp. 271+vii, with 282 illustra-tions. 1977. St Louis: Mosby. £24·80

A collection of isolated topics, each by a different author is bound to be uneven, but the general standard of this book is high and some of the chapters are outstanding. The book opens in fine style with an excellent review of surgery of the rheumatoid hand, marred only by the occasional absence of clear guidance on the selection of procedures. The chapter on scoliosis in adults, without saying anything new, contains much that may be unfamiliar but helpful to the less specia-lized orthopaedic surgeon dealing with back problems. The account of replantation of amputated limbs utilizing micro-surgery is splendidly practical and commendably brief; its guidelines should avert some foolhardy operations in this field. In the chapter on the rheumatoid knee there is a wel-come realization of the importance of correlating the type of prosthesis with the extent of joint damage. However, although the overall account is informative and well worth reading, the follow-up is too short and the case summary on p. 181 is so dreadfully printed that it should be used as an example of how not to do it.

Sports medicine of the neck and back is discussed in a manner which is probably appropriate to practice in the United States, but would find little application in Great Britain. The account of the problem back contains some use-ful clinical tips and has an admirable emphasis on psycho-logical aspects. The treatment of hip fractures is faithfully catalogued, detailing the problem, the difficulties and the suggested answer. The now almost statutory review of embolic problems is adequate rather than sensational, but the combi-nation of social compassion and cost-effectiveness in the Californian management of severely handicapped children is exciting and could usefully be imitated here.

The binding is elegant, the illustrations clear and the text printed on good quality paper; but £24·80 is much too much for this small book and may well price it out of the British market.

A. GRAHAM APLEY



[illegible]oclip®

[illegible] easy ligation in all surgical procedures.

Hemoclips are uniquely shaped to give really reliable three-stage closure action. Firstly, they are easy to position. Secondly, they close first at the tip, ensuring that the vessel will not slip out during compression.

And thirdly, the jaws are cross serrated for extra grip to give positive and complete occlusion.

Four different clip sizes, sterile, are available to meet all operative requirements and there is a choice of no less than twenty different types of applying forceps.

All Hemoclip products are available from Downs Surgical, so send the coupon now for full details.

fucidin

FUCIDIN (sodium fusidate B.P.)

Dosage:

Adults: 500 mg (2 capsules) 3 times daily with food.
Children: 20-40 mg/kg body weight daily in 3 divided doses with food.

The standard dose may be doubled for initial therapy in severe infections.

Adverse reactions and precautions:

After 14 years of widespread clinical use no pattern of toxicity to Fucidin has emerged. Gastro-intestinal upset occurs in some patients taking oral Fucidin. This can be minimised by taking the capsules with food or using Fucidin Enteric Coated Tablets. In some patients treated with either oral or I.V. Fucidin, jaundice has been reported. It has been extremely difficult to decide whether Fucidin, other drugs or the infection itself was responsible. Fucidin is excreted mainly in the bile and liver function tests should be carried out in patients with liver dysfunction, when used for prolonged periods or when administered in conjunction with other drugs which may compete for the same excretory pathway.

Product Licence No: 0043/5019.

Each capsule contains 250 mg sodium fusidate B.P.

VAMIN* GLUCOSE

Presentation
Clear, straw-coloured solutions for intravenous use containing all essential amino acids, and a balanced mixture of non-esse amino acids in each 1,000ml. (pH 5.2). Carbohydrate, as glucose (100g/l), has bee added as an energy source. Electrolytes a present, but these may need supplementi according to patient needs.
Nitrogen per litre: 9.4g. corresponding to about 60g. of first-class protein. Caloric content per litre: 650 Kcal., of which 410 are provided by glucose.

Uses
Vamin Glucose is indicated in conditions protein depletion where oral or intragastr feeding is impossible or impracticable.

Dosage and Administration
Depending on the individual protein requi ment, 0.5-2.0 litres intravenously per day.

Infant dosage: 30-40ml. per kg. body weight in 24 hours.

Contra-indications, Warnings, etc.
Irreversible liver damage and severe uraemia when dialysis facilities are not available. Care should be taken when administering this solution to diabetic patients.

Side effects: As with all hypertonic infusio solutions, thrombophlebitis may occur wh peripheral veins are used.

Package Quantities
Bottles of 100ml., 500ml. and 1,000ml.

NHS price:
£2.50, £6.75, £12.50

Product Licence 0022/0030

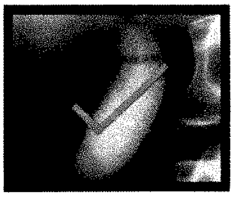
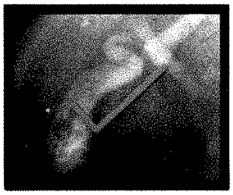
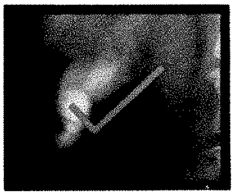
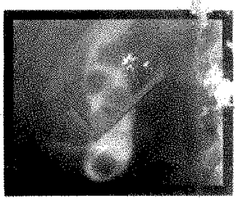
Chendol

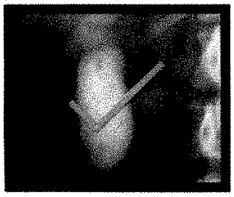
What proportion of stones are suitable

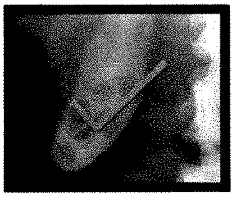


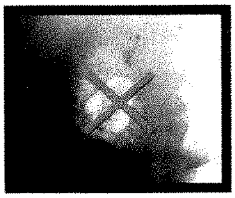


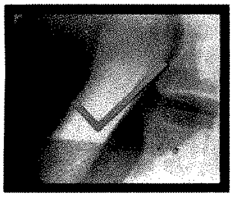


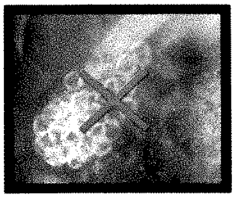


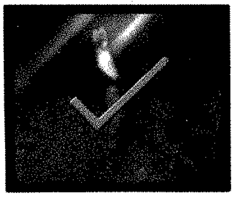












80%

Chendol can remove gallstones without surgery

Chendol solubilises 80% of all gallstones

CHENDOL acts on all mixed stones and cholesterol stones that are not calcium coated by reducing the amount of cholesterol secreted into the bile. Precipitated cholesterol is solubilised.

INDICATIONS For dissolution of gallstones. Cholesterol stones coated with calcium, or stones composed of bile pigments are not dissolved by chenodeoxycholic acid

DOSAGE The present clinical evidence suggests that optimum results will be obtained on a dose level of 10–15 mg per kg body weight daily in divided doses

CONTRAINDICATIONS, WARNINGS, ETC CHENDOL should not be administered to patients with radio-opaque calcified gallstones nor to patients with non-functioning gall'bladders nor to patients with chronic liver disease, nor with inflammatory diseases of the small intestine and colon.

CHENDOL should not be administered to women who may become pregnant

Results of recent studies have demonstrated a 93% success rate in the U.K.[1] and 81% in the U.S.A.[2] for solubilising cholesterol rich radiolucent gallstones in suitable patients.

CHENDOL is generally well tolerated, the only side effects reported to date are diarrhoea and pruritus. It has been found that after a slight reduction in dose for a few days, diarrhoea ceases and the dose can then be gradually increased to the former level Laboratory monitoring should accompany treatment

Each CHENDOL capsule contains 125 mg of chenodeoxycholic acid

Available in securitainers of 100 capsules – N H S cost £13 50 per pack
500 capsules N H S cost £65 00 per pack

Obstructions of the bile duct*

LORD SMITH OF MARLOW†

SIR WILLIAM MACEWEN was not only a towering figure in the surgical history of Britain, he was, from the accounts of all those who knew him, intensely individualistic, a man who inspired contemporaries and successors alike with the desire to copy, to emulate if they could. Sir Gordon Gordon-Taylor, in his Cavendish Lecture of 1958 entitled 'On tradition', pointed out that there are some traditionalists who themselves founded a lasting personal tradition, and as examples he cited Rutherford Morison, Wilfred Trotter, Grey Turner and Macewen. Gordon-Taylor himself was individualistic to a degree and it is to me pleasant, and nostalgic, to recall 'G.-T.' today, for he was not only extremely kind to me when I was a very young surgeon but largely responsible for stimulating in me a particular interest in the surgery of the pancreas, liver and bile ducts. It was G.-T. who said to me in the 1940s, 'If this is the field you're interested in, go to Boston and watch Dick Cattell operate'—good advice, indeed, which I took and consequently saw the most beautiful operating I have ever seen, as well as starting a close friendship which lasted until the untimely death of Dr Cattell at the early age of 62. He, too, was immensely individual in his approach to major surgical problems and in his management of patients. One cannot help wondering what any of these three, Macewen, Gordon-Taylor and Cattell, would have made of the suggestion today that important decisions in surgery should be 'consensus' decisions, taken by a committee rather than by a single surgeon in whom, in any case, final responsibility must remain vested.

All of this leads me to say that I do not think I need apologize, in [illegible] Macewen Lecture upon bile duct obstruction, for starting by saying that this will largely be an account of a personal assault, over a period of rather more than thirty years, upon the problems posed by one single particularly difficult variety of obstruction and that, though I shall refer from time to time to the work of those who have influenced my own thinking, if there be some who have come hoping for a comprehensive survey of everything that has been written upon all varieties of biliary obstruction, they will be disappointed.

Although I obtained my Fellowship and was already engaged in surgical practice before World War II, it was in 1946 that I became a consultant at St George's Hospital, and it is of the 31 years that have followed of which I shall speak. Records going back over a period as long as that are necessarily incomplete, and although I kept from the start personal records of patients in the field of surgery that I had decided interested me most, the figures I am about to quote will be a few short of the actual total number of patients treated.

Between May 1946 and July 1977 I operated upon 3527 patients with biliary obstruction (*Table I*). The fact that this series includes more than twice as many traumatic bile duct strictures as gallstone obstructions does not, of course, mean that strictures are more common than stones in the common bile duct but simply that surgeons are in general happy to refer strictures to a specialized centre, particularly if the patient has already had several unsuccessful operations, whilst they will deal with the gallstone obstructions themselves. It is of bile duct strictures that I shall mainly talk to you today, but first I shall briefly refer to the other causes listed and make a few personal comments about these.

Malignant obstruction

Of the primary cancers, we need spend little time upon carcinoma of the gallbladder invading the porta hepatis and occluding the hepatic duct system. This tumour is almost always highly malignant and even palliation of the jaundice is usually difficult to achieve,

---

* The Sir William Macewen Lecture, delivered in Glasgow, November 1977.

[illegible] ary [illegible] ore [illegible]).

[illegible] th[illegible] [illegible] surgeon ex[illegible] the [illegible] of a [illegible]ced patient and failing to mak[illegible] [illegible]nite diagnosis, or making an incorrect diagnosis of sclerosing cholangitis if a biopsy from tissue adjacent to the tumour is reported as showing merely fibrosis and a few inflammatory cells. The proper use of cholangiography, preoperative and peroperative, from above (transhepatic) and below the lesion by endoscopic retrograde cholangiopancreatography (ERCP) will eliminate most, but not all, of the errors in diagnosis.

A few tumours of this kind are resectable (*Fig*. 3), continuity of the biliary tract being restored by an adaptation of the technique I shall describe shortly in dealing with surgery for benign hilar strictures. For most, however, palliation of the biliary obstruction is all that can be achieved. This may be effected by dilatation of the malignant stricture and the insertion, as a stent, of a T tube or transhepatic tube (*Fig*. 4), including the ingenious U tube operation described by Terblanche and his colleagues (1972); by intrahepatic cholangiojejunostomy (Longmire and Sanford, 1949) (*Fig*. 5), or, occasionally, by intrahepatic cholangiocholecystostomy (*Figs*. 6, 7 and 8) in those

a *b*

Fig. 6. Intrahepatic cholangiocholecystostomy; identification and exposure of a dilated intrahepatic duct.

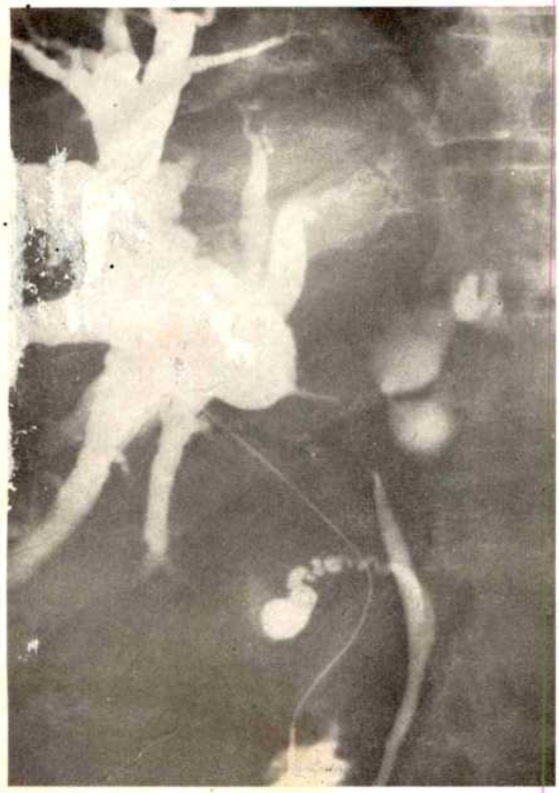

Fig. 7. Carcinoma of the common hepatic duct shown by percutaneous transhepatic cholangiography. Some contrast medium gets past the stricture and part of the gallbladder can be seen. Note the proximity to the dilated intrahepatic ducts, allowing cholangiocholecystostomy.

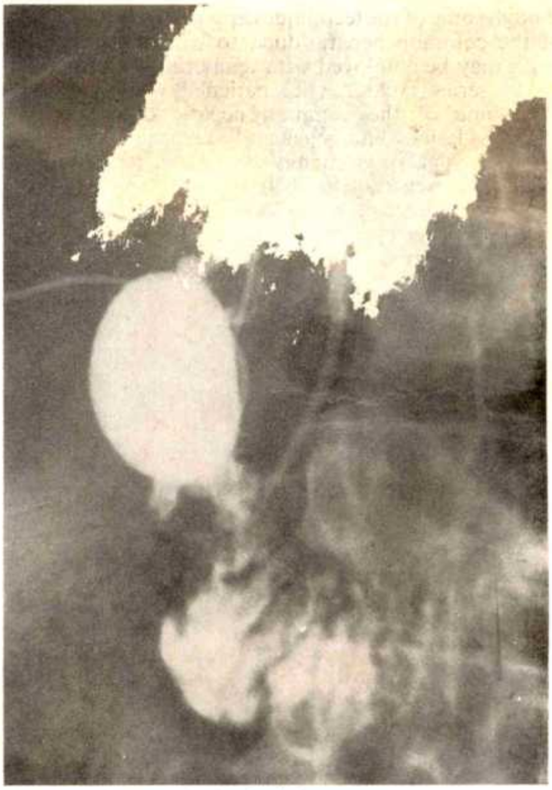

Fig. 8. Intrahepatic cholangiocholecystostomy; a post-operative cholangiogram through an indwelling tube shows contrast medium reaching the duodenum via anastomosis, gallbladder, cystic duct and common bile duct.

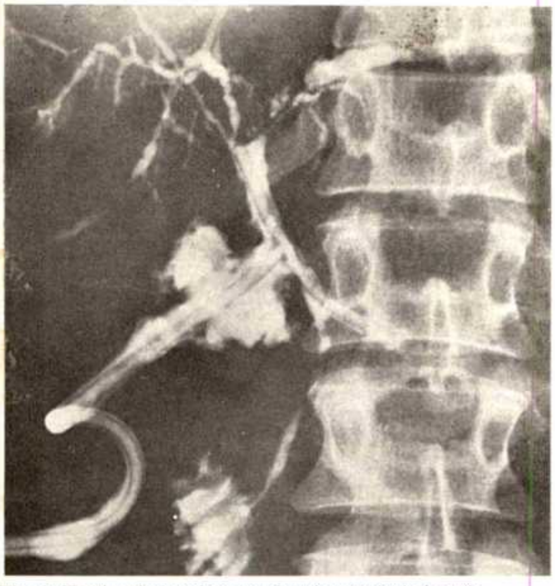

Fig. 9. T tube cholangiogram showing typical chronic sclerosing cholangitis

cases where the gallbladder is normal and the cystic duct joins the common bile duct low down, well away from the tumour. In contradistinction to carcinoma of the gallbladder, primary carcinoma of the common hepatic duct often grows slowly and is slow to disseminate. Resection, if possible, and palliation of the jaundice if not, are therefore well worth while and patients will often live for several years thereafter.

Carcinoma of the hepatic duct system is not infrequently confused with a much rarer condition, chronic sclerosing cholangitis, of which 39 cases are included in my series. Here the strictures are commonly multiple, the intrahepatic and extrahepatic biliary tree being diffusely and widely involved, the cholangiographic appearances being usually quite different from those of a carcinoma (*Fig.* 9). However, there is a variety of diffuse carcinomatosis of the duct system which may produce a diagnostic problem, and radiological differential diagnosis can therefore occasionally be difficult.

Treatment of chronic sclerosing cholangitis is unsatisfactory. Improvement has been observed after treatment both with steroids and with immunosuppressive drugs, but the usual course is unfavourable, leading eventually to an intractable biliary cirrhosis.

[illegible] obstructions, 634 [illegible] r periampullary [illegible] all not discuss thes [illegible] that in regard to pa [illegible] for a radical approa [illegible] the years and I d [illegible] interest in total pa [illegible] a [illegible] ctomy' is likely to lea [illegible] tients [illegible] ng cured, whatever the [illegible] s.

Traumatic strictu

I move on now to my main topic, traumatic stricture of the bile duct. Regrettably in almost all of the 1554 patients with strictures, the cause was damage to the duct during a cholecystectomy, and lest it be thought that these are mostly patients from abroad seeking help in Britain, *Table II* shows the countries in which the first operation had been performed. As can be seen, some three-fifths of the strictures, more than 900 of them, were 'home-grown'.

Every so often there appears in print the suggestion that to damage a bile duct during a cholecystectomy is just bad luck, a natural hazard as it were, and never really the surgeon's fault—in fact, just as likely to happen with an experienced consultant as with an inexperienced junior. This is not borne out by my figures, for, as shown in *Table III*, of 400 unselected cases a consultant was responsible in 62 (15 per cent), whilst in 338 (85 per cent), a junior had been operating on his own.

How does the injury occur? First, technical difficulty and severe inflammatory pathology obscuring the anatomical landmarks are not common causes of this disaster. All too frequently the patient is a thin, young woman, the ducts mobile and normal or small in calibre and the surgeon responsible describes the operation as easy and damage to a duct as beyond his comprehension. The more common causes include an inadequate incision and poor exposure, poor illumination, poor anaesthesia, poor assistance, ignorance of possible anatomical anomalies and a failure to make certain identification of the anatomical structures. Maingot (1977) is right in adding fatigue as a factor, commenting 'It is a mistake to carry out biliary tract surgery towards the end of a long session of operations when the surgeon may be tired or under some tension'. It is also a mistake to insist upon removal of every millimetre of a normal cystic duct.

Diagnosis of trauma to a major duct

Damage to a major bile duct may be recognized during an operation (*Fig.* 10), diagnosed in the immediate postoperative period, or identified at a later date, after the patient has left hospital.

If the operation has been completed without evidence that anything untoward has occurred, the early onset of a deepening obstructive jaundice will naturally arouse suspicions that the common bile duct or common hepatic duct has been accidentally ligated. More commonly, a main extrahepatic bile duct may have been incised, torn, crushed or even divided. In this circumstance, from the day of the operation a profuse discharge of bile will indicate a serious duct injury. In a high proportion of cases of this kind the discharge of bile eventually stops, but optimism on this score is shown to be an illusion as the patient slowly becomes icteric. Sometimes the fistula will reopen with relief of the jaundice and then close again with return of the jaundice. This sequence of events is a not uncommon way for a bile duct injury to present. The picture may be further complicated by subphrenic or subhepatic sepsis as the result of infected bile pooling under the liver or above. Occasionally, the injured duct may turn out to be an anomalous duct, but unfortunately this is only rarely the case.

A relatively minor ductal injury may result in a temporary fistula which eventually dries up completely, leaving a patient who is apparently perfectly well. Later a stricture develops at the site of the injury; the existence of biliary stasis is signalled by the onset first of attacks of cholangitis and later by the slow development of obstructive jaundice. Occasionally, this may occur after the main common hepatic duct has been totally divided and the patient then develops a spontaneous internal fistula into the duodenum. Such a fistula does not result in a spontaneous cure, for,

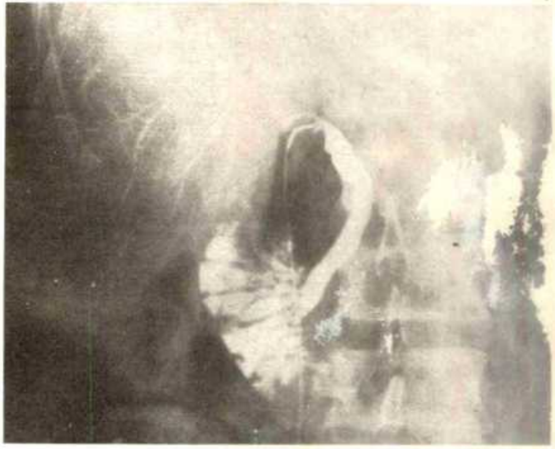

Fig. 10. Peroperative cholangiogram through the cystic duct, clearly showing an injury to the common hepatic duct just above the cystic duct.

being small and not lined with epithelium, the stoma is inadequate from the start and tends to contract with the passage of time. Biliary stasis is further complicated by the development of stones and biliary sludge within the intrahepatic bile ducts; clinically, the patient develops intermittent jaundice and recurrent cholangitis with bouts of high fever, perhaps with rigors.

One further way in which a duct injury may manifest itself should be mentioned. Leakage of bile into the peritoneal cavity does not always produce a severe peritonitis. The evil reputation of biliary peritonitis is probably due to the fact that the leakage is so often of infected bile, leading to a rapidly spreading bacterial peritonitis, rather than merely chemical irritation. Occasionally a cholecystectomy is followed by a slow progressive distension of the abdomen in a patient who remains remarkably well. It is possible for 4–5 litres of bile to collect in a greatly distended abdomen in this way, the patient complaining merely of the increase in abdominal size and pressure and the difficulty of breathing caused by this, a mild icterus developing from the absorption of bile pigment.

Preoperative management
The presence of major injury to a bile duct is usually evident and the necessity for a further operation clear. Preoperative investigations should include a full blood picture, liver function tests, electrolyte estimation and an estimate of renal function. Correction of any deficit brought to light must include administration of vitamin K by intramuscular injection. The patient will often be pyrexial with a high leucocyte count and it is important to decide whether the infection lies within the bile ducts, in other words whether the patient has cholangitis, or whether it is due to a subphrenic abscess which should be drained, leaving the repair of the bile duct injury to a later date. Immediately before operation percutaneous transhepatic cholangiography is useful to outline the dilated bile ducts within the liver and to demonstrate the site of the stricture. This is a more helpful use of radiology than mere demonstration of the duct below the lesion by ERCP.

Operative technique
If it is recognized during the operation that the common bile duct or common hepatic duct has been damaged, immediate repair should be carried out, employing the smallest possible number of the finest sutures necessary to reconstruct the duct. A T tube should be placed in the duct through a separate stab incision, and the majority of surgeons with particular experience in the surgery of the injured duct believe that this T tube should be left in place for a period of at least 3–4 months.

When operating to repair a long-standing stricture of the common hepatic or common bile duct, an ample incision giving good exposure is mandatory. Before approaching the porta hepatis the surgeon should routinely mobilize thoroughly both lobes of the liver and the whole of the right colon so that the latter can be removed completely from the right upper quadrant of the abdomen and packed away downwards and to the left, in order to secure a wide exposure in the area where the ductal damage has occurred.

The antrum, pylorus and duodenum are carefully mobilized away from the liver and retracted downwards. In dissecti[illegible]um from the porta hepatis, a fistula betw[illegible] hepatic duct above the stricture and [illegible] duodenum is quite often present an[illegible] specifically be looked for. If found, it is [illegible] small opening into the duodenum is [illegible]. The dilated common hepatic duct abo[illegible]ure is sought in the dense scar tissue in [illegible]atis, if necessary a needle and syringe being used to identify the duct. Occasionally the injury is at such a high level that there is no common hepatic duct left and in the scar tissue are discovered the ends of the right and left common hepatic ducts, opening independently. The duct or ducts are mobilized as far as possible and dissected free from scar tissue. Using probes and operative cholangiography the anatomy of the duct system above the stricture is displayed and the interior of the duct carefully inspected to determine the level at which the normal epithelial lining is visible. Bile from the intrahepatic ducts is taken for culture; often this is very dirty, containing a great deal of biliary mud and sometimes small stones. It is important before proceeding with the repair to wash out the duct system, and the most effective way of doing this is to insert a catheter that fits tightly into the opened duct and to distend the intrahepatic biliary system by injecting, slowly, up to 60 ml of sterile water or saline. The catheter is then pulled out and as the fluid rushes out from the liver it brings with it solid debris often lying high inside the smaller intrahepatic ducts. This procedure is repeated several times until the fluid returns clear. The operation can now continue.

The anastomosis
The late Dr Cattell in the Lahey Clinic recommended, even in late cases where several unsuccessful attempts had been made at repair, that end-to-end anastomosis of the bile duct should nevertheless still be carried out (Cattell, 1947). Today most surgeons working in this field believe that a better long term result is likely to be obtained with anastomosis of the common hepatic duct to the jejunum and this is the most popular procedure at the present time.

In 30 years of endeavour I have changed my mind more than once in regard to the technique likely to yield the best results and the stages through which my own thoughts have passed [illegible] considered not only possibly of interest bu[illegible]o those anxious to work in this somewhat exciting field.

On the face of it, one m[illegible] imagine that the repair of a divided hollow tu[illegible]ch as a bile duct, would best be effected by end-[illegible] anastomosis, and as a young surgeon immedia[illegible]ter World War II I accepted without much fur[illegible]ought Dr Cattell's assurance that this was, in [illegible] case.

In my early cases, therefo[illegible] upon an end-to-end anastomosis (*Figs.* 1[illegible]), [illegible]nly for a recently divided duct but also in the late case after excision of the resultant stricture. Like Cattell I dissected out the contracted lower end of the duct and, mobilizing the head of the pancreas, shifted this up into the porta hepatis so that, even in the case of a hilar stricture, anastomosis could be performed without tension. Like Cattell, however, I found that far too many patients returned, having initially done well, with a recurrent stricture at the site of the anastomosis (*Fig.* 13). By the late 1940s I had abandoned end-to-end anastomosis for an established stricture, particularly the

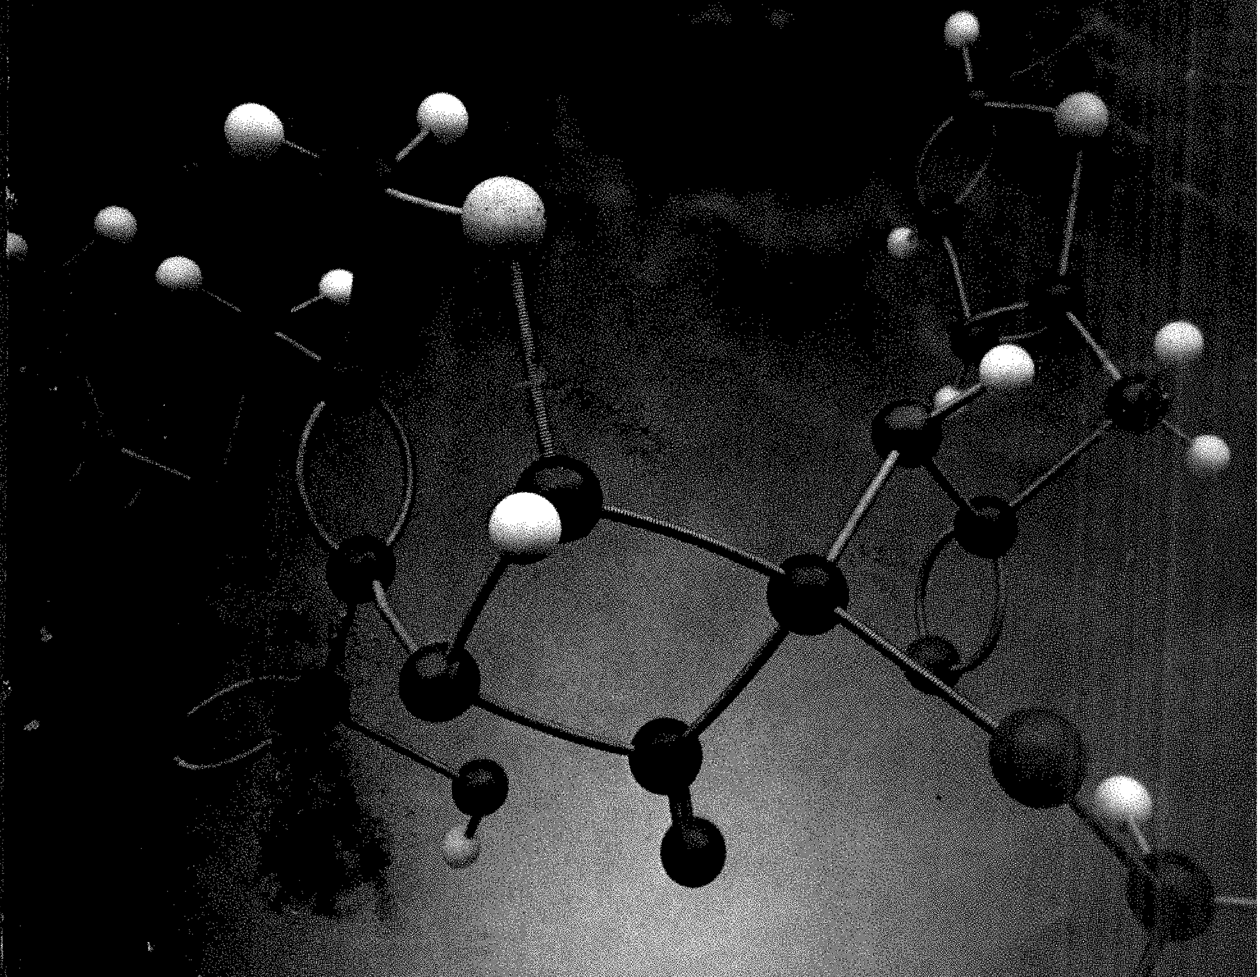
MSD announces
the discovery of

Mefoxin®

Cefoxitin sodium, MSD

INJECTION

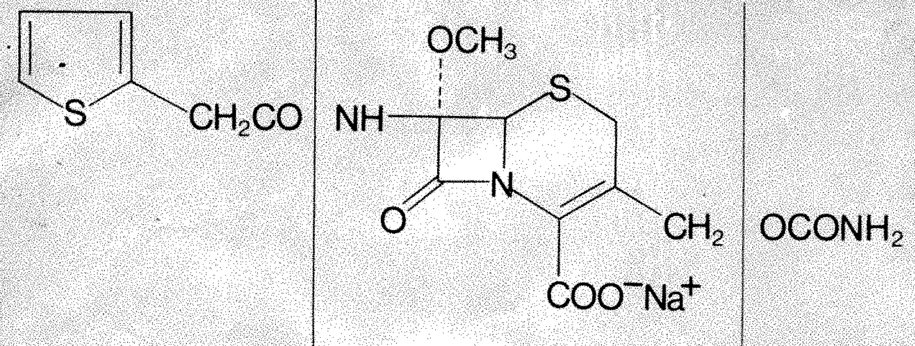
First of the cephamycins



A new class of antibiotics

'Mefoxin' is derived from cephamycin C, a naturally occurring antibiotic substance produced by *Streptomyces lactamdurans*. This naturally occurring antibiotic has been modified in the MSD Research Laboratories to enhance its therapeutic usefulness.

'Mefoxin' has a unique mol[illegible] e offering outstanding clinical benefits [illegible]nd a [illegible]ecif clinical profile.



Thienylacetyl side-chain:

enhances activity against Gram-positive pathogens

Cephamycin nucleus:

provides bactericidal activity against a wide range of pathogens, Gram-negative in particular. 7α-methoxy group protects against β-lactamase degradation

Carbamo side-chai

protects antibiotic metabolised

▼Prescribing information

Indications

'Mefoxin' is a broad-spectrum bactericidal antibiotic indicated for the treatment of infections caused by susceptible strains of Gram-positive and Gram-negative pathogens both aerobic and anaerobic.

'Mefoxin' has been clinically effective not only in infections due to antibiotic-sensitive organisms, but also in infections due to organisms resistant to one or more of the following antibacterial agents: penicillin, ampicillin, carbenicillin, tetracyclines, erythromycin, chloramphenicol, cephalosporins, kanamycin, gentamicin, tobramycin, and sulphamethoxazole-trimethoprim.

Many Gram-negative pathogens are resistant to penicillins and cephalosporins through the action of the β-lactamases which are produced by these pathogens. 'Mefoxin' is remarkably stable in the presence of these bacterial β-lactamases, both penicillinases and cephalosporinases. Hence, the clinical efficacy of 'Mefoxin' extends to many infections caused by such pathogens.

'Mefoxin' is indicated for the treatment of the following infections caused by sensitive bacteria
Peritonitis and other intra-abdominal and intrapelvic infections; female genital tract infections; septicaemia; urinary tract infections; respiratory tract infections; bone and joint infections; and skin and soft-tissue infections.

'Mefoxin' is indicated for adjunctive therapy in the surgical treatment of infections, including abscesses, infection complicating hollow visceral perforations, cutaneous infections, and infections of serous surfaces, whether caused by aerobes, mixed aerobes and anaerobes, or anaerobes.

Microbiology

'Mefoxin' is active *in vitro* against

Aerobic bacteria

Gram-positive cocci including *Staphylococci* (including coagulase-positive, coagulase-negative, and penicillinase-producing strains); Group A beta-haemolytic streptococci *(Streptococcus pyogenes)*; Group B beta-haemolytic streptococci *(Streptococcus agalactiae)*; *Streptococcus pneumoniae (Diplococcus pneumoniae)*; other streptococci (except group D streptococci including enterococci, most strains of which are resistant, e.g. *Streptococcus faecalis*) *Gram-negative cocci including* *Neisseria gonorrhoeae* (including penicillinase-producing strains), *Neisseria meningitidis* *Gram-negative rods (facultative anaerobes) including* *Escherichia coli, Klebsiella pneumoniae*, Klebsiella spp., *Proteus mirabilis* *Proteus* (indole-positive) *Proteus vulgaris, Proteus rettgeri, Proteus morganii, Haemophilus influenzae, Serratia marcescens*, Providencia spp., Salmonella and Shigella spp.

Anaerobic bacteria

Gram-positive cocci including Peptococcus spp.; Peptostreptococcus spp., Micro-aerophilic streptococcus *Gram-positive rods including* *Clostridium perfringens*, Clostridium spp., Eubacterium spp., *Propionibacterium acnes*. *Gram-negative cocci including* Veillonella spp. *Gram-negative rods including* *Bacteroides fragilis, Bacteroides melaninogenicus*, Bacteroides spp. (including both penicillin-susceptible and penicillin-resistant strains) Fusobacterium spp.

'Mefoxin' is active against some strains of the following bacteria: *Acinetobacter calcoaceticus* var *anitratum (Herellea vaginicola)*, *Acinetobacter calcoaceticus* var *lwoffi (Mima polymorpha)*, *Alcaligenes faecalis*, Citrobacter spp. and Flavo-bacterium spp., Enterobacter spp.

'Mefoxin' is not active against Pseudomonas, most strains of enterococci and many strains of *Enterobacter cloacae*.

Dosage and administration

'Mefoxin' may be administered intravenously or intramuscularly. (See reconstitution directions for each route below.) Dosage and route of administration should be determined by severity of infection, susceptibility of the causative organisms, and condition of the patient.

Therapy may be started while awaiting the results of susceptibility testing.

Dosage. The usual adult dosage is 1 g or 2 g of 'Mefoxin' every eight hours. (See chart.)

In adults with renal insufficiency, an initial loading dose of 1 g or 2 g may be given. After a loading dose, the following recommendations for *maintenance dosage* may be used as a guide.

Usual adult dosage

Type of infection	Dose	Fr
Uncomplicated	1 g	Ev (o ev
Moderately severe or severe	2 g	Ev (x ev
Infections generally needing antibiotics in higher dosage	3 g (2 g)	Ev (E

Maintenance dosage of 'Mefoxin' in renal function

Renal function	Creatinine clearance (ml min)	
Mild impairment	50-30	
Moderate impairment	29-10	
Severe impairment	9-5	(
Essentially no function	<5	(

In the patients undergoing haemodialys 2 g should be given after each haemod dose should be given as indicated in th

Intravenous administration: reconstitut Injection BP. 1 g is soluble in 2 ml. Alth soluble, for intravenous use it is prefera Injection BP to the 1 g vial or the 2 g via withdraw entire contents of vial into sy

For direct intravenous injection, 'Mefox

Out[illegible] [illegible]ical benefits

Wide-ranging activity ag[illegible] [illegible]ram-ne[illegible]ative and Gram-positive pathogens, anaerobes a[illegible] [illegible]as aerobes.

Unusually high resis[illegible] [illegible]-lactamase degradation.

Highly active against [illegible]oides *fragilis* and strains of *E. coli*, Serratia, Klebsiella spp. and Proteus spp. (including indole positive strains) resistant to other antibacterial agents.

Offers high levels of active antibiotic in the body.

A record of relative safety comparable to the penicillins.

Prime indications include:

- Peritonitis, and other intra-abdominal and intrapelvic infections.
- Female genital tract infections
- Septicaemia
- Skin and soft tissue infections
- Bone and joint infections
- Urinary tract infections
- Respiratory tract infections (e.g. inhalation pneumonia)

Specific clinical profile

'Mefoxin' is exceptionally valuable wherever Gram-negative pathogens and anaerobes are involved in mixed infections. When mixed infections are suspected, therapy may be started while awaiting the results of susceptibility testing.

Mefoxin®

First of the cephamycins

the vein over a period of 3 to 5 minutes or may be given through the tubing when the patient is receiving parenteral solutions.

An intermittent intravenous infusion of 'Mefoxin' may be employed when large amounts of fluid are to be given. However, during infusion of the solution containing 'Mefoxin' it may be advisable temporarily to discontinue administration of any other infusion solution at the same site (by using an appropriate IV infusion set).

A solution of 'Mefoxin' may also be given by continuous intravenous infusion (see below for compatibility and stability).

Intramuscular administration ONLY

Reconstitute 'Mefoxin' 1 g with 2 ml of Water for Injection BP or 0.5% or 1% lignocaine hydrochloride (without adrenaline) solution. 'Mefoxin' is given by deep injection into a large muscle mass. Avoid injection into a blood vessel.

Compatibility and stability

A solution of 'Mefoxin' in Water for Injection BP may be added to the following solutions: 0.9% Sodium Chloride Injection BP, 5% or 10% Dextrose Injection BP, Dextrose and Sodium Chloride Injection (5%/0.9%, 5%/0.45%, or 4.3%/0.18%), Lactated Ringer's Injection USP, 5% Dextrose in Lactated Ringer's Injection, 5% or 10% invert sugar in water, 10% invert sugar in saline solution, 4.2% Sodium Bicarbonate Injection BP, M/6 Sodium Lactate Injection BP.

'Mefoxin', as constituted to 1 g/10 ml with Water for Injection BP, Water for Injection BP preserved with parabens or benzyl alcohol, 0.9% Sodium Chloride Injection BP or 5% Dextrose Injection BP maintains satisfactory potency for 24 hours at room temperature, for 96 hours under refrigeration, and for 13 weeks in the frozen state.

'Mefoxin' can be administered concomitantly with such antibiotics as gentamicin, tobramycin, carbenicillin or amikacin. When 'Mefoxin' is administered with another antibiotic, they should not be mixed in the same syringe.

Contra-indications

'Mefoxin' is contra-indicated in persons who have shown hypersensitivity to cefoxitin. In the absence of clinical experience, 'Mefoxin' should not be administered to patients who have shown hypersensitivity to cephalosporins.

Precautions

There is some clinical and laboratory evidence of partial cross-allergenicity between cephamycins and other β-lactam antibiotics, penicillins, and cephalosporins. Severe reactions (including anaphylaxis) have been reported with most β-lactam antibiotics.

Before therapy with 'Mefoxin', careful inquiry should be made concerning previous hypersensitivity reactions to β-lactam antibiotics. 'Mefoxin' should be given cautiously to penicillin allergic patients.

Any patient who has demonstrated some form of allergy, particularly to drugs, should receive antibiotics cautiously. If an allergic reaction to 'Mefoxin' occurs, the drug should be discontinued.

The total daily dosage should be reduced when 'Mefoxin' is administered to patients with transient or persistent reduction of urinary output due to renal insufficiency (see 'Dosage and administration') because high and prolonged serum antibiotic concentrations can occur from usual doses.

Interference with laboratory tests

A false-positive reaction to glucose in the urine may occur with reducing substances but not with the use of specific glucose oxidase methods.

Use in pregnancy

Use of the drug in women of childbearing potential requires that the anticipated benefits be weighed against possible hazards. Reproductive and teratogenic studies have been performed in mice and rats and have revealed no evidence of impaired fertility or harm to the foetus due to 'Mefoxin'. There are no controlled studies with 'Mefoxin' in pregnant women.

Nursing mothers

'Mefoxin' is excreted in human milk.

Infants and children

Pending the outcome of clinical trials in progress, the conditions for use of 'Mefoxin' in infants and children remain to be defined.

Side effects

'Mefoxin' is generally well tolerated. Side effects rarely require stopping treatment and [illegible]

Local reactions

Thrombophlebitis has occurred with intravenous [illegible]. Pain, induration and tenderness after intramuscular [illegible] have been reported.

Allergic

Maculopapular rash [illegible] allergic reactions have been noted rarely.

Gastro-intestinal

Diarrhoea has been reported rarely.

Blood

Transient leucopenia and [illegible]. Some individuals, particularly [illegible] may develop positive direct Coombs tests during therapy with 'Mefoxin'.

Liver function

Transient elevations [illegible] alkaline phosphatase have been reported rarely.

Kidney

Elevations in serum creatinine and/or [illegible] have been observed. The role of 'Mefoxin' in changes [illegible] is difficult to assess, since factors predisposing [illegible] or to impaired renal function usually have been [illegible]

OUR THANKS TO ALL THOSE BRITISH SURGEONS WHO'VE HAD A HAND IN OUR SUCCESS.

For as long as British Surgeons have been wearing latex Surgeons' gloves, we have been making them.

While British medical research and discovery has been improving surgical procedures, ongoing research and improved rubber technology has developed a glove that precisely fits the needs of today's British Surgeon.

The continuing input of suggestions and comments by Surgeons plays a vital part in this evolution and this is why we'd like to thank you, the British Surgeon, for the hand you've had in our success.

very high hilar stricture (*Fig.* 14), in favour of hepaticojejunostomy, employing a Roux loop (*Fig.* 15) (Smith, 1964a). I continued to use a temporary indwelling tube as a stent and in 1949, for the first time, I used, instead of a T tube from below, a straight length of tube running transhepatically (*Fig.* 16). I described 15 years' experience with the transhepatic tube in 1964 (Smith 1964b), and quite soon it became apparent from publications that other surgeons favoured a tube inserted in this way, some of them having clearly come to this decision independently, in particular Praderi of Montevideo, to whose thoughtful papers I would pay tribute (Praderi, 1974; Praderi, Delgado et al., 1974; Praderi, Mazza et al., 1974).

The results of hepaticojejunostomy splinted by a transhepatic tube were an improvement upon end-to-end anastomosis, but nevertheless I was disappointed to find that there were still too many failures for any degree of satisfaction. Those due to established biliary cirrhosis one could understand, but in those cases in which a favourable result was expected, some 25 per cent returned with evidence of restenosis at the site of the anastomosis. Why, I asked myself, should the anastomosis restenose after removal of the transhepatic tube, even if this had been left *in situ* for 6 or even 12 months? I came to the conclusion that, at least in the very high recurrent hilar stricture, the reason

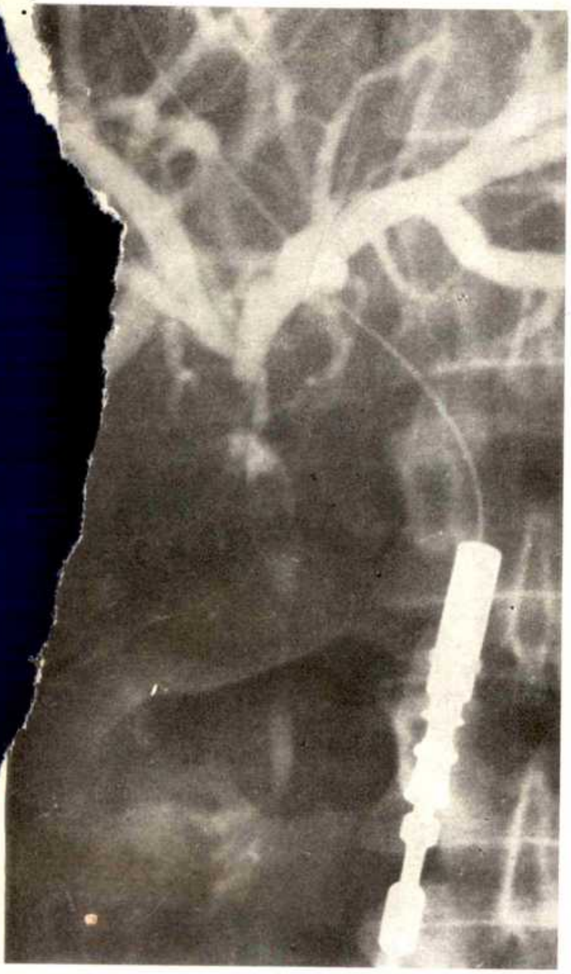

Fig. 14. Transhepatic cholangiogram showing a high hilar stricture of the common hepatic duct and also that a gallbladder remnant containing stones is still present.

probably lay in the impossibility of achieving, with a traditional sutured anastomosis, an adequate apposition of the bile duct epithelium and jejunal epithelium.

As I wrote in 1972

> Trauma to the bile duct during cholecystectomy often does occur at a very high level. Moreover, if the injury leaves, say, half a centimetre of common hepatic duct below the liver, this half centimetre of usable common hepatic duct may disappear as a result of repeated unsuccessful attempts at repair. It is thus far from uncommon for a surgeon to explore a stricture of the bile duct and to find that the normal criteria for success cannot possibly be achieved, and that in particular it does not appear possible to appose accurately the lining of the common hepatic duct above the stricture either to the lining of the distal duct below or to the epithelium of a loop of jejunum brought into the porta hepatis. It is little use in these cases to core out of the thickened capsule of the liver a cylinder of scar tissue and to call this a duct, for anastomosis of a cylinder of scar tissue without an epithelial lining to the jejunum, whilst it will serve for a while, is bound to restenose at a later date.

It seemed to me that if access to the epithelial lining of the bile duct is so inadequate through the mass of scar tissue in the porta hepatis that accurate suture to the epithelial lining of the jejunum appears to be impracticable, a successful repair could still be achieved if in some way the epithelial lining of the jejunum could be placed through the zone of fibrosis and in contact with the duct lining. This is the principle of the 'mucosal graft' operation, which I introduced into my practice 10 years ago (Smith, 1969, 1972) (*Figs.* 17–19). It is effected by cutting away a disc of the seromuscular coat of the jejunum in order to expose the mucosa and make a diverticulum which can be used as a mucosal graft to line the area where the epithelium is missing. A variety of methods have been employed in order to place this graft *in situ.*

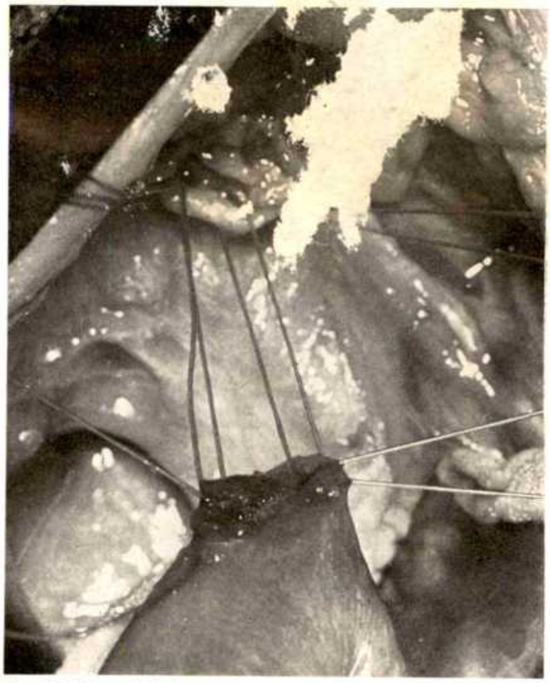

Fig. 15. Hepaticojejunostomy: magnified view of the first sutures placed between the common hepatic duct and jejunum. This operation will not succeed unless jejunal and duct epithelium can be apposed without tension.

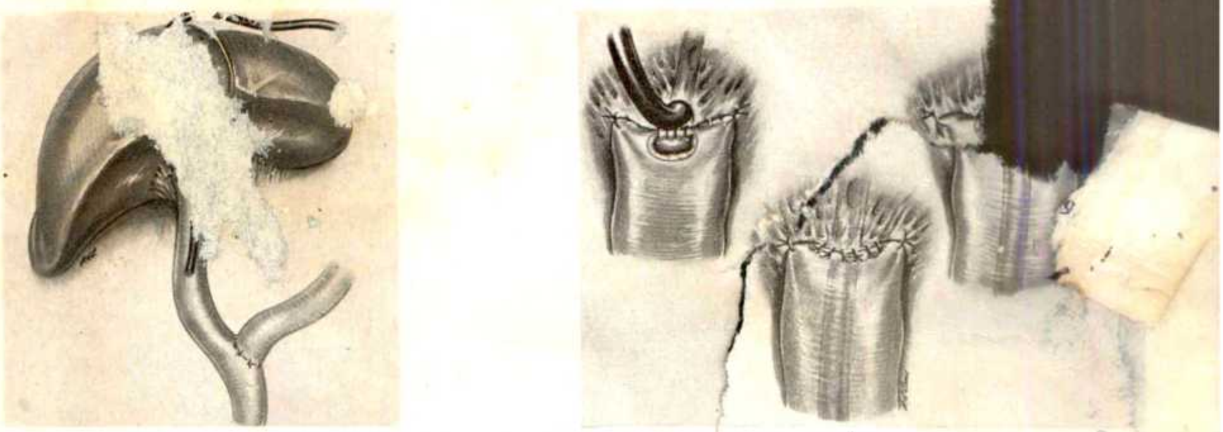
Initially a specially constructed Y tube was employed which, with its two limbs inserted into right and left hepatic ducts, carried the jejunal mucosa up into contact with the epithelial lining of the hepatic duct system, the tube later dropping out into the jejunum and being passed per rectum (*Fig.* 17*c*). This was a stage of transition and led on to a technique employing both a mucosal graft and a transhepatic tube, the graft ensheathing and being attached to the tube so that the sleeve of jejunal mucosa is drawn up through the scar tissue around the duct and well into the intrahepatic duct system (*Fig.* 18).

No sutures are used in the junction of hepatic duct epithelium and jejunal epithelium but the weight of the Roux loop is supported by suturing it t thickened capsule of the liver around the du Redivac drain is placed below the liver adjacer anastomosis and usually a second Redivac positioned below the diaphragm where the hepatic tube emerges from the dome of the liver.

Postoperatively, the transhepatic tube is attached to a low tension electric pump. Suction is discontinued



a *b*

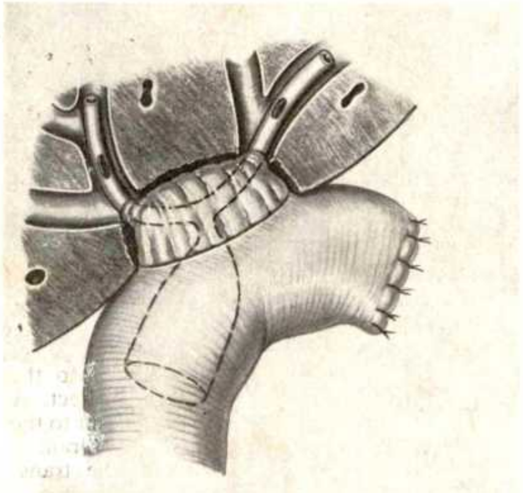
a *b*



c

Fig. 17. Mucosal graft replacement of totally excised common hepatic duct.

as soon as bile ceases to be recovered from the Redivac tubes, which are then removed. The transhepatic tube is then allowed to drain freely into a bag and after 7–10 days is spigotted. The patient is discharged home after 12–14 days, having been taught to wash the tube through once daily with sterile water or saline. Four months postoperatively the patient is readmitted to hospital for 48 h for a general assessment, including a tube cholangiogram, bacteriological examination of bile and liver function tests, after which the tube is removed (*Figs.* 18–19).

It is my belief that the combination of the mucosal graft with a transhepatic tube is a useful one for the following reasons:

1. However high the ductal injury, the mucosa of the jejunum can be placed in contact with the epithelial lining of the hepatic duct system.
2. Splinting the junction of duct to jejunum with an indwelling tube is probably useful and the transhepatic tube can be left in as long as is desired.

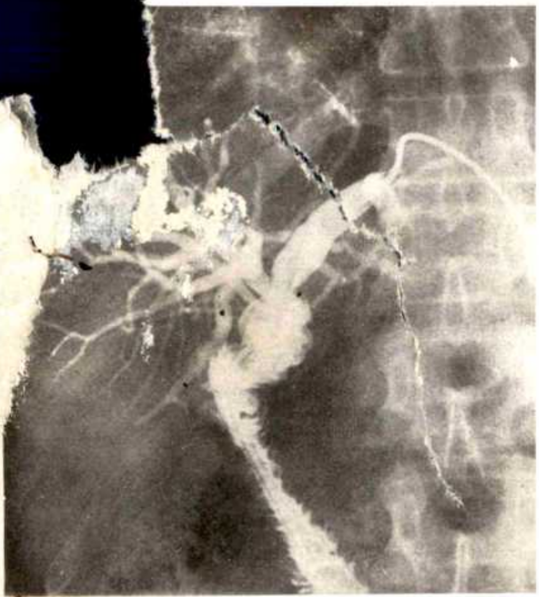


Fig. 18. Repair of hepatic duct stricture with mucosal graft and transhepatic tube (postoperative tube cholangiogram).

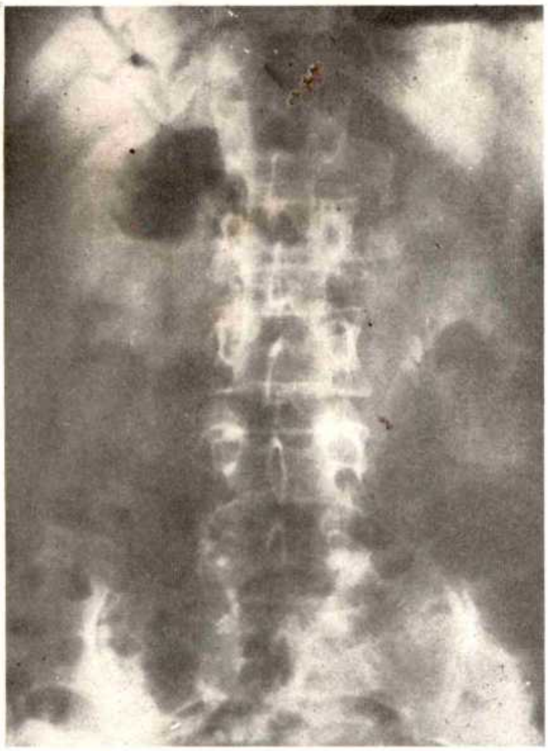

Fig. 19. Repair of hepatic duct stricture with mucosal graft and transhepatic tube ('Pepsicologram' 1 year later).

3. The only stitches employed are those anchoring the Roux loop to the capsule of the liver, and the junction of bile duct epithelium to jejunal epithelium is sutureless.

4. Diversion [illegible] n is achieved in the p[illegible] ative [illegible] ing the transhepatic tu[illegible] a lo[illegible] amp.

5. The transhep[illegible] tube [illegible] duct system to be washed out pos[illegible] eratively as well as at operation. It further allows radiological studies (*Figs.* 18, 19) and permits bile to be taken for culture whenever desired.

In the case of a duct injury so high that no common hepatic duct remains, the right and left hepatic ducts being identified separately, two transhepatic tubes are employed, both attached to the same jejunal mucosal pocket. This is also the technique of reconstruction employed after resection of a carcinoma of the common hepatic duct.

Results

Repair of a bile duct stricture employing the mucosal graft technique is simpler and easier to perform than repair employing a standard suture technique and it takes considerably less time. This is reflected in the operative hazard. Nearly 600 operations of this kind have now been performed, the last 227 without mortality.

The percentage of patients permanently cured is more difficult to assess, for how are we to measure what is permanent? Following other techniques patients return with recurrence of trouble 2, 5, even 20 (in one case) years later and we have no right to assume that this will prove different after a mucosal graft operation.

Analysis of the results of all patients after a mucosal graft operation for whom reliable records were available 2 years postoperatively showed the following: 85 per cent were anicteric and without symptoms, divided into 45 per cent with normal liver function tests and 40 per cent with abnormal liver function tests (usually an elevated serum alkaline phosphatase); 11 per cent had unsatisfactory results which had been anticipated at operation on account of (*a*) a long history and established biliary cirrhosis, or (*b*) a long history and secondary sclerosing cholangitis with multiple intrahepatic ductal strictures, or (*c*) a long history and severe chronic purulent cholangitis with multiple intrahepatic calculi; 4 per cent had restenosis where a favourable result had been anticipated (all of these have been or will be reoperated upon and the odds favour a final successful result).

In that the great majority of patients suffering restenosis of a hepatico-jejunal anastomosis present evidence that this is taking place during the first year after operation, these 2-year figures suggest that with a mucosal graft type of repair restenosis becomes an uncommon cause of an unsatisfactory result. No technique is likely ever to eliminate restenosis altogether or solve the problem of the liver already damaged beyond repair. Here a new donor liver would seem to be the only hope.

I cannot end this evening without expressing not only my gratitude that I should have been accorded the very great honour of being allowed to deliver a lecture commemorating the name of that very great surgical pioneer, Sir William Macewen, in a university and city which has in many other ways contributed so greatly to British and to world surgery, but also my sense of extreme pleasure and personal enjoyment that I should find myself delivering this lecture before so many old friends and colleagues. It has been for me an occasion I shall never forget.

[illegible] infusion in experimental refractor[illegible]

S[illegible]ITH AND J. N. NORMAN*

[illegible] contribution of primary myocardial [illegible] the [illegible]athogenesis of refractoriness of shock to [illegible]ional therapy is in direct contradiction to the [illegible]ly advocated clinical practice of infusion of large [illegible]mes of fluid in shock resuscitation. A standard [illegible]ine haemorrhagic shock model, in which refractory [illegible]ck is induced by maintaining an arterial blood [illegible]ssure of 40 mmHg for 2 h, has been used to assess [illegible] effects of volume infusion to maintain a central [illegible]ous pressure of 0–2 mmHg for a further 2 h and [illegible]he tolerance of such an infusion by the heart in refractory shock.

Fluid infusion ensured significantly better figures for oxygen balance than in those animals where additional fluid was not given, and the volumes required appeared to be well tolerated by the shocked myocardium.

Primary myocardial failure does not appear to be a major aetiological factor in refractory shock, and provided that the usual monitoring parameters are recorded, volume infusion remains a major part of shock resuscitation.

A NUMBER of theories have been advanced to explain the resistance to conventional therapy of certain patients in severe shock. Wiggers, in 1942, was one of the first to suggest a role for primary myocardial failure, and since then other workers have not only supported a primary myocardial contribution but have also identified a myocardial depressant factor, believed to be elaborated by the ischaemic pancreas (Brand and Lefer, 1966).

It has been well established, however, that in the resuscitation of severe shock, adequate volume infusion is essential, usually requiring infusion of fluid, in addition to blood transfusion, in volumes up to two or three times the estimated blood volume (Harkins, 1941; Hunt, 1972).

The basic 'Wiggers' model failed to take account of this clinical phenomenon and the discrepancy between experimental and clinical facts seemed worthy of fuller evaluation.

Methods

Adult dogs were fasted overnight, anaesthetized with sodium pentobarbital 25 mg/kg body weight, intubated and allowed to breathe room air spontaneously. Using a clean but non-sterile technique, both femoral vessels bilaterally were isolated and cannulated. This allowed monitoring of mean aortic and central venous pressures, assessment of cardiac output by the dye dilution method, withdrawal of arterial blood samples and arterial haemorrhage into a heparinized reservoir. On insertion of the first cannula, total heparinization was ensured by injection of a solitary bolus of 0·3 mg/kg body weight. A Swan–Ganz catheter was inserted into the pulmonary artery via the right jugular vein to monitor pulmonary artery pressure and to obtain venous blood samples.

Oesophageal temperature was monitored throughout and core temperatures maintained at 37±2 °C by a simple heat cage. An electrocardiograph was recorded continuously via subcutaneous electrodes.

Once stability of the preparation was confirmed (*see below*), refractory shock was induced by arterial haemorrhage to maintain mean aortic press[illegible] mmH[illegible]t a 2-h hypotensive period. Initi[illegible] this involv[illegible]s withdrawal of blood through a Watson–Ma[illegible]pump, the maximum bleed-out volume being rea[illegible] after 75–90 min (Wiggers et al.. 1948). Thereafter, decompensation of the microcirculation began and reinfusion from the reservoir was essential to avoid too severe a reduction in pressure (Wiggers and Ingraham, 1946). At the end of 2 h the remaining reservoir blood was reinfused and the animals were allocated randomly to one of two groups. In one group (10 dogs) no additional fluid was reinfused, i.e. the classic Wiggers model; in the other (15 dogs) functional normovolaemia was ensured by infusion of sufficient of a standard colloid/crystalloid perfusate to maintain central venous pressure at 0–2 mmHg. Observations were continued for a further 2 h, after which the animals were sacrificed.

The perfusate used consisted of a mixture of saline, Dextran 40 (40 ml/l) and Dextran 70 (340 ml/l) with added calcium chloride (2·7 mmol/ml) and potassium chloride (8·0 mmol/l) and the solution was buffered to pH 7·30±0·05.

To ensure that the preparation was stable, at least twice before haemorrhage and at 15-min intervals during the experiment, measurements were made of cardiac output, of mean aortic, central venous and pulmonary artery pressures and of temperature and heart rate. Arterial and mixed venous blood samples were obtained for blood-gas analysis (partial pressures and total content), acid base, haemoglobin, haematocrit and lactate estimations. From these it was possible to calculate stroke volume by dividing cardiac output by pulse rate; total peripheral resistance by dividing arterial pressure by cardiac output; oxygen availability as the product of cardiac output and arterial oxygen content; and consumption as a product of cardiac output and arteriovenous oxygen difference. By plotting oxygen consumption graphically and relating the individual figures to a zero of the resting value of 100 per cent, it was possible to calculate an oxygen debt when the figures were below zero and attempted repayment of the debt when the figure was greater than 100 per cent. By calculating the areas below each curve a cumulative figure of oxygen balance could be obtained (*Fig* 1). In those animals given no additional fluid initially, 500 ml of Dextran 70 were infused over 15 min at the end of a 4-h study and the cardiovascular parameters were remeasured after a further 15 min before sacrifice.

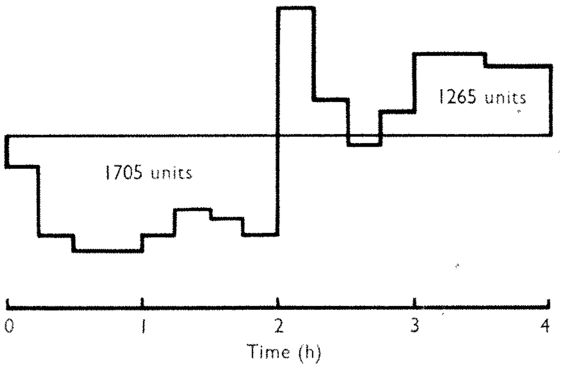

Fig. 1. Oxygen balance in dogs given blood plus perfusate.

Results

The mean resting v[illegible] was computed at 100 per cent and all other [illegible] tained were expressed as a percentage of [illegible] ight results for each parameter in [illegible] e obtained and these have been p[illegible] figure for each of the 2-h perio[illegible] plus or minus the standard error of the m[illegible] tical analysis was performed by the Student [illegible] paired or unpaired data as appropriate.

As shown in *Table I*, both groups were comparable as regards mean body weight, maximum bleed-out volume and the proportion of the maximum bleed-out volume reinfused to avoid too severe hypotension during the 2-h hypotensive period. The dogs given additional fluid required a mean volume of 89·16 ± 10·15 ml/kg to ensure a positive central venous pressure of 0–2 mmHg throughout the 'recovery' phase.

Hypotensive phase: Both groups demonstrated similar haemodynamic and biochemical changes during the 2-h hypotensive period. Both cardiac output (16·04 ± 0·87 per cent) and stroke volume (14·20 ± 1·17 per cent) were reduced from a resting value of 100 per cent. There was a twofold increase in total peripheral resistance (204·17 ± 9·19 per cent). There was a reduction in oxygen availability and a less marked decrease in total oxygen consumption (15·24 ± 0·76, 63·88 ± 3·67 per cent, respectively), resulting in a cumulative oxygen debt of −2649 arbitrary units. There was a progressive, sustained increase in arterial lactate (800·89 ± 43·19). pH, $P\mathrm{o}_2$, $P\mathrm{co}_2$ and bicarbonate mirrored the changes described and have not been reported in detail.

'Recovery' phase (*Table II*)

Following reinfusion of blood, the dogs given no additional perfusate showed sub-resting values for central venous pressure, had persisting tongue cyanosis and were considered to be hypovolaemic. The group reinfused with blood alone demonstrated a persistently reduced cardiac output (52·24 ± 5·10 per cent) and stroke volume (49·09 ± 5·33 per cent) with an associated increase in peripheral resistance (121·71 ± 6·56 per cent). Mean oxygen availability (57·35 ± 6·56 per cent) was below the resting value of 100 per cent. Mean oxygen consumption was 95·58 ± 3·22 per cent of resting and the cumulative oxygen debt increased to −4007 units after a further 2 h.

In the group given additional perfusate to restore functional normovolaemia, the results were quite different. Cardiac output was increased to 186·62 ± 7·91 per cent and stroke volume to 196·33 ± 10·82 per cent of resting. Total peripheral resistance was reduced to a mean of 57·92 ± 2·90 per cent, all three differences being significant relative to the group given blood alone (P < 0·001).

Mean values for oxygen availability (127·17 ± 16·26 per cent) and consumption (121·98 ± 6·56 per cent) were significantly higher (P < 0·001) and the oxygen debt was significantly lower (−440 units).

Statistical analysis by the Student t test for paired data:
* P < 0·0001; ** P < 0·002.

Effect of infusion of Dextran 70 (*Table III*)

In the group given blood alone for the 2-hour recovery phase, the effect of an infusion of 500 ml of Dextran 70 at the end of the experiment was studied and parameters assessed after a further 15 min. Cardiac output was increased to 134·14 ± 9·06 per cent and stroke volume to 143·90 ± 7·63 per cent of the resting value, the difference between these and the results before infusion of Dextran 70 being significant (P < 0·001). Total peripheral resistance was significantly reduced (53·22 ± 2·23 per cent —) from the 121·71 ± 3·94 per cent before infusion of the Dextran 70 bolus (P < 0·002). This figure was not significantly different from the 57·92 ± 2·90 per cent resting value shown in the group given additional perfusate throughout the recovery period.

Discussion

The effects of haemorrhage seen during the 2-h hypotensive period are well established both experimentally and clinically. Initially, consequent upon the reduced venous return, there was a reduction in both cardiac output and stroke volume. Hypovolaemia stimulated catecholamine release (Longerbeam et al., 1960) which in turn produced marked peripheral vasoconstriction as demonstrated by a twofold increase in total peripheral resistance. Adrenergic stimulation produced chronotropic cardiac stimulation with significant tachycardia.

Because of lowered cardiac output and peripheral vasoconstriction peripheral perfusion was impaired, with interference in capillary flow and transport of nutrients, including oxygen (Appelgren and Lewis, 1970). In response to hypoxia there was interference with cellular metabolic function and a transfer to anaerobic energy production. This has been confirmed in the present study by an increasing acidosis and an eightfold increase in arterial lactate.

Control of the microcirculation has been shown to be dependent on local oxygen levels (Stalker, 1970) and to be adversely affected by local acidosis and accumulation of metabolites. In response to severe hypoxia, more and more of the capillary field has become dilated with further embarrassment of cellular nutrition. As the hypoxic insult persisted, disruption of cellular microstructure began with the release of deleterious lysosomal enzymes, which in turn aggravated the interference in cellular and visceral function (Baue, 1968).

The point at which this process becomes irreversible has not been clearly defined, but might be the point at which reinfusion of blood from the reservoir became essential to avoid too severe hypotension (Wiggers and Ingraham, 1946). If not reversed, persistent hypoxia and acidosis would contribute to the disturbance in cardiac output by an effect on the coronary microcirculation, but the evidence available would suggest that this would be a secondary phenomenon.

In the present study, by the time reinfusion of remaining reservoir blood was commenced after 2 h of hypotension, the stage of severe impairment of cellular function had been reached, so that although the term 'recovery' has been used because of literary acceptability, the final 2 h of the experiment is the period of established refractory shock. It is with this phase that the priority for further study lies.

The results obtained from the animals in which the classic Wiggers method was followed, i.e. replacement of absolute blood volume only, are very similar to Wiggers' own—low cardiac output and stroke volume, persistent increase in total peripheral resistance and continuing whole body hypoxia (Wiggers, 1942). Using the same experimental method, other workers have produced similar results, and have, like Wiggers, supported primary myocardial failure as the most important aetiological factor in irreversible shock (Lefer et al., 1967). Lefer and Martin have continued to demonstrate a myocardial depressant factor, believed by them to be elaborated by the ischaemic pancreas in severe shock states (Lefer and Martin, 1970). Ledingham and his colleagues have confirmed the presence of a myocardial depressing toxin, but have shown that, although it was demonstrated after 4 hours of haemorrhagic hypotension to 40 mmHg, it was not present after 2 h (Fisher et al., 1973). In the present study, refractory shock was well established before 2 h, at which time no depressant factor was likely to be elaborated. In addition, the concept of primary myocardial failure must be viewed critically in the light of the well-established clinical practice of aggressive volume replacement in shock resuscitation. For these reasons, the results obtained in the present study when perfusate was infused to restore functional normovolaemia as judged by a pos[illegible] central venous pressure of 0–2 mmHg must be [illegible]ed of critical importance.

Central venous pressure was [illegible] as the criterion of adequate volume infusion because of its wide use in clinical practice and because of the great variations in pulmonary artery pressures, both in individual experiments and in the series as a whole. However, the increase in cardiac output to 186 per cent of the resting value without elevation in venous pressure above the preselected value was believed to represent efficient cardiac function, at least in the short term. The parallel rise in stroke volume, and recorded pulse rates of resting or below resting figures, confirmed that the increased output was achieved inotropically. In this respect, it should be noted that the animals given no fluid additional to the reservoir blood at the time of reinfusion had a persistent tachycardia, with venous pressures below the recorded resting values. The sequence of events is believed to be as follows: provided that volume replacement is adequate, there is microcirculatory dilatation in response to peripheral hypoxia; the reduction in total peripheral resistance allows more ready increase in cardiac output, and, if venous return can be maintained, it seems likely that at least in the short term, cardiac output can be increased to above resting values, presumably in an attempt to satisfy tissue needs for oxygen. Quite clearly, the myocardium cannot continue to function thus indefinitely, and the reserve available will depend on age, pre-existing myocardial disease and the expected duration of the increased demands—hence Ledingham's critical time of 4 h in experimental conditions.

We have no data on left ventricle performance, because the standard methods available to assess this involve either a thoracotomy or indirect measurement of $LV\,\mathrm{d}p/\mathrm{d}t_{\max}$, which has been shown to be variable both at low and high flow states, especially when the use of catheter transducers inserted peripherally is involved. It is seldom that left and right ventricles fail independently in pathological states, and hence a normal central venous pressure was considered to imply satisfactory loadings.

It should also be noted that, even in those animals that remained in a low-output, vasoconstricted hypovolaemic state throughout the 4 h of study, the response to a 500-ml infusion of Dextran 70 was to increase cardiac output and stroke volume, with reduction in tachycardia and total peripheral resistance. This was achieved with no pathological elevation in central venous pressure. This would be consistent with the work of Hardy's group, who have transplanted the hearts of dogs in irreversible haemorrhagic shock to healthy recipients to sustain life for up to 1 week's observation (Hardy et al., 1975).

The relationship between cardiac output and tissue oxygen reserve has been established in unshocked dogs. Increased oxygen tensions following exposure to hyperbaric oxygenation to 3 atmospheres absolute in dogs subjected to total body washout to zero Hb was accompanied by normal cardiac output and 100 per cent survival when red cells were reinfused (Norman, 1975). In shocked animals, the use of steroids was followed by rapid restoration of a positive oxygen balance, and by near to resting values of cardiac output and total peripheral resistance (Smith and Norman, 1978). In the present series, however, the animals [illegible] alone remained in a low-output, vas[illegible]sted state, despite an increasing oxygen debt, presumably because of the loss of venous return.

While no conclusions could be drawn about reversible shock, or in [illegible] shock state (Wiggers and Ingraham, 1946), from [illegible]reported results, the gross discrepancy between irreversible shock and our refractory shock model could well be due to the differences in volume replacement. It should be noted however, that, despite adequate volume replacement, increased cardiac output and presumed satisfactory microcirculatory perfusion, the cumulative oxygen debt incurred in the hypotensive phase was not repaid in full after 2 h of normovolaemia. Although part of the reduced total peripheral resistance could be due to the lowered whole blood viscosity consequent on haemodilution to a haematocrit of 67 per cent of the resting value (Sunder-Plassmann et al., 1972), the majority was considered to be due to persistent peripheral dilatation caused by local hypoxia and acidosis. There can be no doubt that myocardial failure is likely to occur if output remains at such high values, but peripheral vasomotor collapse rather than primary myocardial failure is suggested as a more likely causative factor in refractory shock.

The absence of any difference in the figures for arterial lactate is strange, but the variation in individual results was wide, and in the group given additional fluid, the washout of lactate was likely to contribute to the levels remaining high despite improvement in oxygen consumption (Bergentz et al., 1969).

Conclusions

The primary problem in refractory shock is microcirculatory motor collapse, secondary to prolonged tissue hypoxia and the consequences of it. Provided venous return is maintained, there is no evidence of primary myocardial failure, although it is suggested that this may occur as a later feature caused by high output failure combined with the effect of hypoxia and acidosis on the coronary circulation.

Volume replacement alone is not considered adequate resuscitation in refractory shock, as evidenced by above-resting values for cardiac output and stroke volume and by a persistent total oxygen debt.

Sequential patterns of haemodynamic and metal changes in experimental hypovolaemic shock.
I. Responses to acute haemorrhage

J. PARDY AND H. A. F. DUDLEY*

SUMMARY

Little is known about cardiorespiratory changes during the development of hypovolaemia. This study attempts to provide such information and compares the period of bleeding with that of established hypovolaemia.

Eleven anaesthetized and ventilated greyhounds were bled and analyses of cardiopulmonary function made at fixed intervals both during and after haemorrhage. Six sequential patterns of cardiopulmonary and metabolic change were recognized. It was apparent that bleeding caused the first three phases of change, recovery from the effects of bleeding the next two and steady hypovolaemia the last. The event of bleeding is the main factor that elevates total peripheral resistance and reduces tissue perfusion with consequent lowering of oxygen consumption and alkalosis secondary to impaired carbon dioxide production; when bleeding ceases these changes partially reverse in a manner characteristic of that induced by the reinfusion of shed blood; and hypovolaemia per se has a relatively weak influence.

These findings provide an explanation for disparities in previous published reports and have obvious clinical implications.

DETAILED studies of the cardiorespiratory changes associated with hypovolaemia have resulted in widely disparate findings concerning the behaviour of certain indices. For example, total peripheral resistance in man has been reported to be invariably raised (Hopkins et al., 1965; Wilson et al., 1965), generally raised, but with considerable variation in that it is sometimes normal or below normal (Cournand et al., 1943; Monson and Shoemaker, 1968), normal (Rossoff et al., 1965) or low (Shoemaker et al., 1966). Similarly, in the hypovolaemic dog, total peripheral resistance has been described as markedly increased (Reynell et al., 1955; Cook and Webb, 1968), slightly or moderately increased (Wiggers, 1950) or 'questionably reduced' (Fowler and Franch, 1957).

Disparities such as those described remain unexplained, possibly because studies of hypovolaemia have been confined almost entirely to the period of established shock and little is known concerning the effects of bleeding. We studied the development of hypovolaemia with the hypothesis that the variation in results might be explained by sequential processes which had been studied at different times.

Materials and methods

Eleven greyhounds with a mean weight of 24 kg were used. Anaesthesia was induced with thiopentone sodium 20 mg/kg i.v. followed immediately by pentobarbitone sodium 6 mg/kg. The animal was then placed supine and remained so throughout the study. A cuffed endotracheal tube was inserted and ventilation with room air maintained by a volume-cycled pump respirator. A thermocouple probe was placed in the mid-oesophagus for the recording of core temperature, and

relaxant anaesthesia was maintained wit
i.v. infusion of pancuronium bromide (Pavul

London.

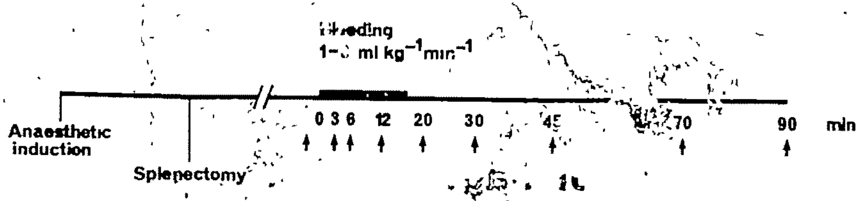

Fig. 1. Plan of the experiment. Measurements were taken at points indicated by arrows.

total peripheral resistance was mean systemic arterial pressure minus central venous pressure.

Base excess was determined from arterial pH, $P\mathrm{co}_2$ and haemoglobin values using an alignment nomogram (Siggaard-Andersen, (1963). The Walsh non-parametric test for related samples was employed for inferential statistics (Siegel, 1956).

Fig. 1 shows the plan of the experiment. After insertion of the cannulas the spleen was removed to obviate the effects of the splenic reservoir of blood, and tidal volume was adjusted so that end-tidal carbon dioxide concentration was approximately 4·5 per cent. The tidal volume setting remained unchanged throughout the experiment. After a period of stabilization baseline measurements were made. Blood was then pumped (Watson-Marlow HR Flow Inducer) from the carotid artery cannula at a constant rate of between 1 and 3 ml kg^{-1} min^{-1} until the systemic arterial pressure began to fall sharply. Shed blood was collected in airless plastic bags containing acid–citrate–dextrose solution (NIH Solution A; Mollison, 1972). After cessation of rapid bleeding, systemic arterial pressure was maintained at approximately 85 mmHg by the removal of further blood or the reinfusion of shed blood via a peripheral vein, until the experiment was terminated 90 min from the start of bleeding. Measurements were made at the times shown in *Fig.* 1.

Results

All dogs but one survived the 90 min of hypovolaemia, the death occurring 80 min after the onset of bleeding (results from this animal acquired during the first 30 min only have been used). Absolute values of indices before bleeding are given in *Table I.* On the basis of qualitative changes in systemic arterial pressure, cardiac output and total peripheral resistance, six sequential patterns of response to haemorrhage could be distinguished (*Table II*). The cardiorespiratory data were assembled as described below for analysis of changes during each phase and the results are shown in *Table III.*

Results are reported as mean ± s.d., and percentage values for indices other than total venous admixture and physiological dead space ratio are of the control value. Because measurements were made intermittently the actual duration of each phase is not known, and the changes reported have only qualitative value except in relation to each other.

Phase I

To enable statistical analysis, the changes in the various indices during the period from the start of bleeding to the arbitrarily chosen point at which systemic arterial pressure had declined by approximately 5 per cent of the pre-bleed level were determined. A number of the values for indices at this point were derived by interpolation. Systemic arterial pressure fell at a rate of 0·6 per cent per minute, cardiac output and pulmonary artery pressure fell by similar proportions, and total peripheral resistance and pulmonary vascular resistance rose. Oxygen consumption, carbon dioxide production and $P\mathrm{aco}_2$ decreased, arterial pH rose and total venous admixture and physiological dead space ratio (physiological dead space/tidal volume) did not change.

Table I: ABSOLUTE VALUES BEFORE BLEEDING (mean ± s.d.)

Mean systemic arterial pressure (mmHg)	168±12
Cardiac output (ml min^{-1} kg^{-1})	183±43
Total peripheral resistance index (dyn s kg cm^{-5})	775±209
Mean pulmonary artery pressure (mmHg)	19±7
Pulmonary vascular resistance index (dyn s kg cm^{-5})	47±15
Oxygen consumption (ml kg^{-1} min^{-1})	8·0±1·3
Carbon dioxide production (ml kg^{-1} min^{-1})	6·5±1·1
pH arterial blood	7·41±0·02
$P\mathrm{co}_2$ arterial blood (mmHg)	39±2
Base excess (mmol/l)	0·5±1·4
Total venous admixture (%)	11±5
Physiological dead space ratio (%)	53±5

Table II: QUALITATIVE CHANGES IN CARDIAC OUTPUT, TOTAL PERIPHERAL RESISTANCE AND SYSTEMIC ARTERY PRESSURE DETERMINING THE SIX PHASES

I: Initial bleeding	CO falls, TPR rises, SAP well maintained
II: Further bleeding	CO falls, insufficient rise in TPR to maintain SAP
III: Late bleeding	CO falls, no change in TPR, SAP falls sharply
IV: Immediately after bleeding	CO unchanged, TPR falls, further fall in SAP
V: Subsequently after bleeding	CO rises, no change in TPR, SAP rises
VI: Steady hypovolaemia	No change in CO, TPR or SAP

CO, Cardiac output; TPR, total peripheral resistance; SAP, systemic arterial pressure.

Phase II

All results reported in this and subsequent phases were derived directly. Because the timing of measurements was fixed while the timing of cardiopulmonary responses varied, data from consecutive measurements could not be correlated with the phases in all animals. During this phase systemic arterial pressure fell from approximately 95 to 75 per cent of the control value at a rate of 3·4 per cent per minute. Changes in all other indices were similar to those observed during phase I.

Phase III

As bleeding continued systemic arterial pressure began to decline rapidly and the removal of blood was slowed or stopped. Systemic arterial pressure fell at a rate of 5·1 per cent per minute, the result of a decline in cardiac output without any increase in total peripheral resistance. The decline in oxygen consumption and carbon dioxide production was greater than

in previous phases, total venous admixture fell and the physiological dead space ratio increased. Arterial pH was elevated despite a decline in base excess.

Phase IV

After cessation of bleeding a sharp fall in total peripheral resistance unaccompanied by any change in cardiac output resulted in a continued decline in systemic arterial pressure. There was no further reduction in oxygen consumption or carbon dioxide production and Pa_{CO_2} rose for the first time. Arterial pH, significantly elevated above control level, fell sharply with the rise in Pa_{CO_2} and a further fall in base excess.

Phase V

Cardiac output and systemic arterial pressure both rose while total peripheral resistance remained unchanged. Oxygen consumption and carbon dioxide production now increased.

Phase VI

During this period of steady hypovolaemia there was no significant change in any index except pulmonary vascular resistance, which increased.

Discussion

The reports of early workers that cardiac output is reduced when blood volume is depleted have not since been disputed. By contrast, there has been a conspicuous lack of unanimity about changes in certain other indices during haemorrhagic shock and to add to the confusion many of the reported changes have been of doubtful or no significance. Suggestions that widely differing findings may be related to the dynamic nature of shock (Walters, 1972) and to the duration and depth of shock (Shoemaker et al., 1967) carry the implication that there are patterns of change in shock and that results will vary according to the stage at which measurements are made. However, those patterns of change which have been described (Kim et al., 1969; Bassin et al., 1971; Vladek et al., 1971) have not explained the disparities between published results.

Three distinctive features of the current study were the rapid measurement of cardiac output by the Fick method made possible by the online system, use of a fixed tidal volume and the performance of analyses during continuous bleeding. These techniques enabled the recognition of six sequential patterns of change hitherto not described. It is important, however, that the limitations of analysis of data acquired by intermittent measurement of a continuously changing process be recognized, especially when the time course is variable. A consequence of the latter was that not all the phases were identified in all the animals, phase II being observed in 7 dogs and phase III in 8. With these considerations in mind, it is clear that the existence of the six phases described can only be inferential.

The cause-and-effect relationships during the phases can be surmised by examination of the data in *Table III*. It will be seen that a number of indices underwent three sequential changes coinciding with

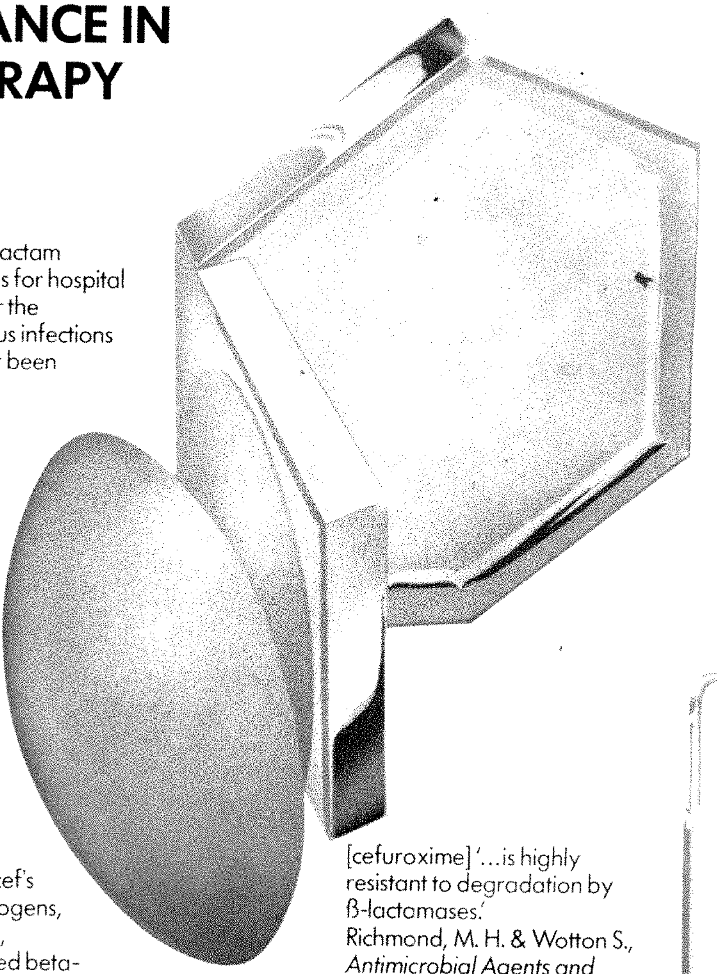
ZINACEF

cefuroxime sodium

A MAJOR ADVANCE IN ANTIBIOTIC THERAPY



Zinacef is a new, broad spectrum, beta-lactam antibiotic offering important advantages for hospital practice. It is particularly appropriate for the treatment of serious, or potentially serious infections where the causative organisms have not been identified or may be mixed.

Greatly enhanced stability to beta-lactamases

The value of commonly used beta-lactam antibiotics is being constantly eroded by the growth of resistant populations of bacteria.
Zinacef has a unique chemical structure with in-built protection against beta-lactamases which effectively places it in a new class of antibiotics.

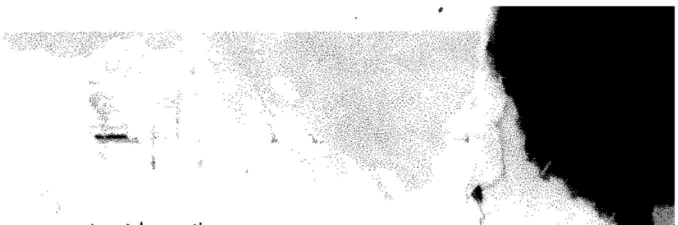
A broader spectrum than most antibiotics

The ability to resist destruction results in a greatly extended clinical spectrum. Zinacef's bactericidal effect extends to many pathogens, both Gram-positive and Gram-negative, resistant or partially resistant to established beta-lactam antibiotics.

[cefuroxime] '...is highly resistant to degradation by ß-lactamases.'
Richmond, M. H. & Wotton S., *Antimicrobial Agents and Chemotherapy* (1976) **10,** 219

With important therapeutic properties

- Zinacef has high bactericidal activity.
- Adequate serum levels are rapidly achieved and are well maintained.
- Zinacef is widely distributed with adequate levels in sputum, bile, bone and cerebrospinal fluid.
- Zinacef is not metabolised, but excreted, active and unchanged, in the urine.
- Zinacef has minimal toxicity, giving a wide margin of safety.
- Clinical trials have shown excellent renal tolerance.
- Zinacef can safely be used in neonates.
- Patient tolerance is excellent both intramuscularly and intravenously.
- Zinacef is compatible with commonly-used intravenous infusion fluids.
- There are no known clinically relevant adverse drug interactions.
- Zinacef can be used with other antibiotics to increase the antibacterial cover.



> …this wide antib[illegible] te[illegible] [Zinacef] a usefu[illegible] infections requiring promp[illegible] [illegible] apy before the causative pathogen has been identified.'

ZINACEF

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 gram and infusion pack of 1·5 gram. All containing cefuroxime as cefuroxime sodium.

Indications
Serious bacterial infection, especially where the organisms have not yet been identified.
Conditions include:
Chest infections
Septicaemia
Soft tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Urinary tract infections
Ear, nose and throat infections
Meningitis
Gonorrhoea

Dosage
Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 gram t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary.
Infants and children: 30 to 100mg/kg/day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in two or three divided doses.
Gonorrhoea: Single dose of 1·5 gram (2 x 750mg i.m. into different sites).

Contra-indications
Hypersensitivity to cephalosporins.

Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria.
Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine.
As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage should be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.

Side effects
Adverse reactions are rare and generally mild and transient, e.g., rashes, gastro-intestinal disturbance, candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).

Storage
The powder in the infusion pack and vials should be stored below 25°C and protected from light.

interpretation of the likely sequence of events wh occurred as a result of bleeding.

Bleeding period

The reduction of venous return with bleeding caus a progressive fall in cardiac output, but the initial rise in total peripheral resistance was sufficient to maintain systemic arterial pressure. Though perfusion pressure was maintained, effective tissue blood flow was impaired, as shown by the reduction of oxygen consumption and carbon dioxide production. This reduction in carbon dioxide production was responsible not only for the fall in Pa_{CO_2}, ventilation being constant, but also for the rise in arterial pH, there being no increase in base excess. With further bleeding, total peripheral resistance increased at a slower rate and systemic arterial pressure was less effectively maintained. Total venous admixture was reduced, probably because the effects of ventilation/perfusion inequalities were lessened and blood flow through anatomical shunts was reduced (Sykes et al., 1970). Physiological dead space increased because a greater proportion of alveoli were not perfused.

Early period after bleeding

Recovery from the effects of bleeding was associated with a sharp fall in total peripheral resistance which is hard to explain. The conventional mechanisms responsible for increasing total peripheral resistance during hypovolaemia are reduced baroreceptor activity consequent upon less stretch and increased chemoreceptor activity secondary to accumulation of metabolites in the glomus tissue. These mechanisms cannot have been reversed when bleeding ceased, however, for there was no increase in systemic arterial pressure (which fell) and almost certainly no increase in perfusion of glomus tissue because cardiac output was unchanged. The phenomenon, also observed in relation to heart rate (Rushmer, 1965), remains unexplained.

Arterial pH, previously elevated despite a reduced base excess, fell sharply at this time because of the combined effects of a rise in Pa_{CO_2} and a further fall in base excess.

Subsequent (phase V) changes during this period included a rise in cardiac output and an improvement in tissue perfusion as evidenced by the changes in oxygen consumption and carbon dioxide production. These changes were remarkably similar to those resulting from the initial reinfusion of shed blood as described in the accompanying paper (Pardy and Dudley, 1979).

Late period after bleeding

Contrasting with the dynamic states during the period of bleeding and immediately after, the 37 min of phase VI were relatively static and the only significant change was a large increase in pulmonary vascular

to be ing cea and (c) hypovolaemia y weak influence on these indices. these conclusions, it is likely that ing during established hypo- with h cause total peripheral resistance to rise and oxygen consumption to fall and that th changes will partially reverse when bleeding stops.

The above concepts provide some explanation the disparities mentioned at the beginning of paper. When measurements have been made incremental bleeds (Kim et al., 1969), the finding reflect the effects of recovery from the prec bleed. When a reservoir system has been empl the results will be affected by whether blood is e or leaving the experimental subject at the t measurement. And in clinical studies, the matc of data to determine patterns of change will hindered by the fact that bleeding may be occurring unbeknown to the investigator.

The data from this study contradict the suggestion that systemic arterial pressure is well maintained during bleeding until total peripheral resistance falls (Kho and Shoemaker, 1967), and do not support the concept that the increase in physiological dead space during hypovolaemia is related to reduced pulmonary artery pressure (Askrog, 1966; Naimark et al., 1968). We suggest that reduced physiological dead space may be related more closely to the reduction of pulmonary blood volume than of pulmonary artery pressure. Finally, comment should be made on the close correlation between changes in pulmonary artery pressure and cardiac output during bleeding (Pardy and Dudley, 1977a). This relationship was not maintained later in shock when pulmonary artery pressure rose more than cardiac output, the result of a greater increase in pulmonary vascular resistance than of total peripheral resistance (pulmonary artery wedge pressure did not change).

The finding that the most marked derangements occur during bleeding has clinical relevance. Bleeding in surgical patients is frequently difficult to detect, and appropriate measurement made on suspicion may be of more value than conventional measurements which tend to recognize only the effects of severe blood loss. Measurements which are practicable include pulmonary artery pressure and end-tidal carbon dioxide concentration.

Discussion

Six phases of haemodynamic and metabolic change were recognized during the reinfusion of shed blood and shortly thereafter. However, the existence of these phases must be accepted with the same provisos mentioned in the previous paper. Reinfusion of shed blood resulted in an immediate improvement in haemodynamic status, with restoration of tissue perfusion as evidenced by the elevation of oxygen consumption and carbon dioxide production. The latter can be attributed to the return of tissue metabolism toward normal, the metabolism of 'excess' lactate formed during anaerobic glycolysis, the mobilization of carbon dioxide from previously poorly perfused tissues and the interaction of infused acid citrate and circulating bicarbonate. These last two factors increase carbon dioxide production relative to oxygen consumption, and this explains the increase in respiratory quotient. The rise in $Pa\text{CO}_2$ secondary to the rise in carbon dioxide production would have been greater but for the reduction in physiological dead space, which improved the efficiency of carbon dioxide excretion.

Oxygen consumption ceased to increase after phase II, while haemodynamic improvement persisted up to and including phase IV. This suggests that tissue perfusion had become maximally effective long before haemodynamic improvement was complete and the return of all the shed blood. As opposed to the early restoration of tissue blood flow, arterial pH did not rise above the pre-infusion level until phase V.

The data in *Table III* indicate that with the reinfusion of shed blood there is an initial tendency for arterial pH to fall; this was principally the result of a rise in $Pa\text{CO}_2$, because there was only a minimal change in base excess. The finding that buffering capacity at this time was little changed may be explained by the counterbalancing of two tendencies; the tendency for buffering capacity to be reduced by anaerobic metabolites entering the general circulation, by infused acid citrate and by metabolism of citrate ions; and the reverse tendency attributable to the metabolism of 'excess' lactate and the neutralization of acid citrate. Because ventilation remained constant and the physiological dead space ratio was not increased, the rise in $Pa\text{CO}_2$ at this time was secondary to the previously described increase in carbon dioxide production. Thus, the initial downward trend of arterial pH is primarily the consequence of increased carbon dioxide production and not of reduced buffering capacity. Identical mechanisms operating in reverse were identified during initial bleeding in the previous study; arterial pH rose because carbon dioxide production was reduced, there being no increase in buffering capacity (Pardy and Dudley, 1979).

As further shed blood was returned, $Pa\text{CO}_2$ began to fall and buffering capacity increased, causing arterial pH to rise. The reduction in $Pa\text{CO}_2$ towards the pre-infusion level was not caused by a decrease in [illegible] production but by a fall in physi[illegible] [illegible] With regard to buffering capacit[illegible] [illegible] would have been operating as w[illegible] [illegible] except that the mobilization [illegible] would probably have be[illegible] [illegible] Therefore, the increase in buffer[illegible] capacity [illegible] principally the result [illegible] 'excess' [illegible] An outline of th[illegible] mechanisms is given [illegible]

The data in this study [illegible] the stateme[illegible] previously made about physiological dead sp[illegible] (Pardy and Dudley, 1979). Certain haemodynam[illegible] inferences of clinical relevance can also be made. Th[illegible] marked improvement in cardiovascular performanc[illegible] after the infusion of blood for only 4 min demonstrates that even a small degree of blood volum[illegible] restoration may be efficacious. The patient in haemo[illegible]rhagic shock should therefore be infused as soon a[illegible] possible with whatever suitable fluid is availabl[illegible] albeit the volume immediately to hand is sma[illegible] (Dudley et al., 1968).

A second point is that while the measurement of arterial pH may permit evaluation of the severity of haemorrhagic shock, the finding of a low pH does not necessarily mean that alkalis should be infused (Andersen et al., 1967). As seen in the current study, restoration of blood volume is associated with spontaneous return to normal of arterial pH, but this may occur quite a long time after haemodynamic recovery. It is to be noted that myocardial contractility in the intact animal (Downing et al., 1965) and in the isolated heart (Opie, 1965) is not impaired until pH falls below 7·1 and raising arterial pH from 7.00 to normal does not improve myocardial action in the acidotic dog (Ledingham et. al., 1972). Nevertheless, pH may fall sharply with initial volume replacement, and in our study arterial pH fell by 0·17 and 0·08 respectively in 2 animals. The likelihood of such a fall in pH is greater when blood volume replacement is rapid.

Therefore, should arterial pH be in the region of 7·1 before resuscitation, it is suggested that blood should not be infused unduly rapidly in the first instance, and that the concomitant administration of a small amount of sodium bicarbonate may be advantageous. If arterial pH is not below 7·2, however, the use of bicarbonate in the hypovolaemic subject without other causes for acidosis (such as dead or damaged tissue) should be restricted.

Finally, the measurement of pulmonary artery pressure would appear to be of greater value than that of systemic arterial pressure in the assessment of both active bleeding (Pardy and Dudley, 1977) and of the effectiveness of blood volume restoration.

B. J. PARDY AND H. A. F. DUDLEY*

SUMMARY

The haemodynamic and metabolic effects which follow the infusion of blood in experimental hypovolaemia have not been studied in detail. The 10 dogs that survived 90 min of hypovolaemia in a study of bleeding (Pardy and Dudley, 1979) were investigated during and shortly after the reinfusion of shed blood using the same techniques.

Data from 9 animals were suitable for analysis. As with bleeding, 6 sequential phases were identified; reinfusion of blood was completed in the fifth phase. Initial reinfusion was associated with a rapid improvement in haemodynamic and metabolic status, although mean arterial pH fell because carbon dioxide production increased. Maximum metabolically effective tissue perfusion was probably attained in phase II, but haemodynamic improvement continued until phase IV. Arterial pH did not rise above the pre-infusion value until phase V, and this rise was the result of a fall in $Pa\text{CO}_2$ *secondary to a reduction in physiological dead space and an increase in buffering capacity.*

Pulmonary artery pressure was superior to systemic artery pressure as a predictor of cardiac output during blood volume restoration. A number of conclusions pertaining to clinical practice are drawn.

WHILE the haemodynamic and metabolic changes during established hypovolaemic shock have been intensively studied and the findings widely reported, few data are available on the exact sequence of events during resuscitation from this state. We therefore continued the study described in our previous paper (Pardy and Dudley, 1979), and analysed in similar detail the changes during and shortly after the reinfusion of shed blood.

Materials and methods

The 10 greyhounds that survived the acute haemorrhage study were reinfused with shed blood previously collected in sterile, airless plastic bags containing acid–citrate–dextrose (NIH Solution A; Mollison, 1972). The warmed blood was returned as a drip infusion via a standard giving set into a peripheral vein at a rate of approximately 30 ml/min. No other fluid was infused.

Analyses of cardiorespiratory and metabolic function were performed as described in the previous study before and 4, 10, 20, 40 and 80 min after starting the reinfusion of shed blood. Values of statistical significance were determined using the Walsh non-parametric test for related samples (Siegel, 1956).

Results

All dogs survived the period of resuscitation from shock, but at the end of the experiment systemic arterial pressure was declining in 3 animals (results from these dogs acquired during the first 40 min only have been used). All results are reported as mean ± s.d. and percentage values for indices other than total venous admixture and physiological dead space ratio are of the pre-bleed value. The data from one animal were discarded because the pre-infusion systemic arterial pressure was 78 per cent whereas the mean systemic arterial pressure for the other 9 dogs was 50±9 per cent. Absolute values for the various indices before reinfusion of blood are given in *Table I*.

The duration of the reinfusion period was 53±17 min, and the resultant cardiorespiratory changes could be separated into six sequential phases. The factors determining placement of results in the various phases are shown in *Table II* and the cardiopulmonary and metabolic data are given in *Table III*.

Table I: ABSOLUTE VALUES BEFORE REINFUSION OF SHED BLOOD (mean±s.d.)

Mean systemic arterial pressure (mmHg)	82±11
Cardiac output (ml min^{-1} kg^{-1})	54±21
Total peripheral resistance index (dyn s kg cm^{-7})	1435±492
Mean pulmonary artery pressure (mmHg)	8±5
Pulmonary vascular resistance index (dyn s kg cm^{-7})	160±102
Oxygen consumption (ml kg^{-1} min^{-1})	6·6±1·6
Carbon dioxide production (ml kg^{-1} min^{-1})	5·4±1·7
pH arterial blood	7·32±0·07
$P\text{CO}_2$ arterial blood (mmHg)	42±4·6
Base excess (mmol/l)	−4·8±3·3
Total venous admixture (%)	8±5
Physiological dead space ratio (%)	60±6

Table II: FACTORS DETERMINING PLACEMENT OF DATA IN THE VARIOUS PHASES

	Relation to reinfusion of shed blood
Phase I	First 4 min
Phase II	4–10 min
Phase III	10–20 min
Phase IV	20–40 min, but not including dogs in which infusion was completed
Phase V	Dogs in which infusion was completed (40–80 min in 5 animals, 20–40 min in 1)
Phase VI	After infusion completed (40–80 min)

Phase I

During the first 4 min, cardiac output rose and pulmonary vascular resistance fell. There were consequent rises in systemic arterial pressure and mean pulmonary artery pressure, and $Pa\text{CO}_2$, oxygen consumption and carbon dioxide production increased.

Phase II

The haemodynamic and metabolic changes of phase I continued except that there were no further significant changes in pulmonary vascular resistance or $Pa\text{CO}_2$. The physiological dead space ratio fell. Analysis of the combined changes during phases I and II showed that there was a significant fall in total peripheral resistance by 32±35 per cent ($P<0·03$), and that the fall in arterial pH was not significant.

in casualty

Because of the high probability of contamination, wound infection constitutes one of the major hazards of any accidental injury and may seriously compromise healing. Although these infections are usually mixed, staphylococci, especially penicillinase producing strains, present a particular problem.

Magnapen combines the broad spectrum activity of ampicillin with the anti-staphylococcal activity of flucloxacillin. Magnapen is therefore bactericidal against the pathogens most likely to cause problems, including penicillinase producing strains.

Magnapen* (ampicillin and flucloxacillin in equal parts) is available as capsules, vials for injection, and fruit flavoured syrup.

Full prescribing information is available on request. *regd.

sults a p hrough techn try. The first part of the work of the reproducibility of this technique using both an infused tube system and a system of subminiature, intraluminal strain gauge transducers. The second part of this report describes a study into the effect that the position of the recording hole on the probe may have in relation to the measured pressure for the lower oesophageal sphincter.

THERE is no doubt that there is a zone of increased pressure situated at the lower end of the oesophagus which acts as a barrier to the regurgitation of gastric contents into the oesophageal lumen. Unfortunately, the accuracy of measurement of this lower oesophageal sphincter pressure presents a significant problem (Pope, 1970; Perez-Avila and Irvin, 1975) and therefore its clinical use is precluded at present. There are two major sources of error, measurement artefact and measurement insensitivity (Dodds et al., 1976).

We have reassessed the reproducibility of lower oesophageal sphincter pressure as measured by the station pullthrough technique using an open-ended, water-infused manometry system and an oesophageal probe equipped with three subminiature, intraluminal strain gauge transducers—the Sensotec EMP3.

One suggested cause of recording infidelity is the actual position of the recording sites on the oesophageal probe (Kaye and Showalter, 1971). To study this we have looked closely at the effect that this has upon the recorded pressure for the lower oesophageal sphincter.

Materials and methods

Equipment

The first part of the study, on the reproducibility of the station pullthrough technique, was performed using two sets of equipment. In one series of studies a triple-lumen polyvinyl recording catheter of 4·5 mm diameter had side holes cut at 5, 10 and 15 cm from the tip (probe A, *Fig.* 1). It was connected to three Statham P23 pressure transducers and each lumen was infused at a constant rate of 27 ml/h by a Braun infusion pump (*Fig.* 2). The pressure variations were recorded on paper by a Grass Polygraph Model 7D eight-channel recorder, to which was also connected a temperature probe placed in the external nares. This effectively monitored the phases of respiration. The subject was asked to indicate when he swallowed by pushing a button.

In the other series of reproducibility tests a pressure probe equipped with three subminiature strain gauge transducers (Sensotec EMP3) was used (probe B, *Fig.* 1). Because this equipment had no infusion apparatus it could be plugged directly into the recording equipment.

In the study that investigated the effect of the position of the recording side hole upon the measured lower oesophageal sphincter pressure, two similar triple-lumen recording catheters were used (tubes 1 and 2 in *Fig.* 1). These were similar to the infusion probe that was used in the first study except that the three recording side holes all lay at the same level in each tube. In tube 1 they lay at 5 cm from the tip and in tube 2 they lay 15 cm from the tip.

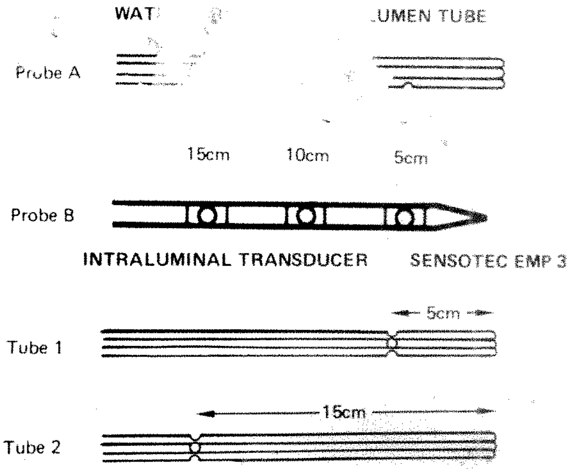

Fig. 1. Distal ends of probes. Probes A and B used in reproducibility study. Tubes 1 and 2 used in study on effect of location of recording side hole.

Table I: SUBJECTS STUDIED

	No.	Age (yr) Mean	Age (yr) Range
Reproducibility study			
Infusion probe	9 (7 M, 2 F)	23·1	21–35
Intraluminal transducer probe	8 (7 M, 1 F)	25·0	23–25
Side hole position study	11 (9 M, 2 F)	23·9	20–33

Subjects (*Table I*)

All subjects were volunteers whose mean age was 24 years (range 20–35 years). None had symptoms suggestive of oesophageal reflux or dyspepsia and informed consent was obtained in each case. The tests were performed after a 4-h fast during which time smoking was also forbidden. In the reproducibility study there were 17 subjects. Nine were tested with the open-tube system and 8 with the Sensotec equipment. Each subject was tested with the same equipment on three occasions. On the first day (day 1) two tests were performed, at 0830 h and again at 1630 h. A further test was performed a week later (day 7), again at 0830 h.

In the second part of the study there were 11 subjects, each of whom was tested on two occasions, once with each tube (1 and 2). These two tests were performed in random order on the same day.

Technique

In all tests the probe (infusion catheter or intraluminal transducer) was passed via the mouth until all three recording sites lay in the gastric lumen (*Fig.* 2). The subject then rested for 15 min. A standard station pullthrough was performed in each case as the patient lay on a couch. The probe was withdrawn 0·5 cm at a time through the lower oesophageal

sphincter into the body of the oesophagus. A minimum of five respiratory cycles was allowed at each station.

Analysis of traces and statistical methods
The lower oesophageal sphincter pressure was taken as the difference between the mean end-expiratory value of the pressure in the sphincter and the mean end-expiratory value of the resting gastric pressure. It was expressed in millimetres of mercury.

Table [illegible]TS WITH INFUSED CATHETER

	Lower oesophageal sphincter pressure (mmHg)

In the reproducibility study the results on different occasions were compared using correlation graphs. In the study on the effect of the side hole position, the results were compared using a paired Student's *t* test.

Results

Reproducibility of the station pullthrough technique
Using the infused manometry catheter there were no differences in the values obtained for the lower oesophageal sphincter pressure when a group of normal subjects was examined from occasion to occasion (*Table II*). A similar pattern emerged when the results obtained using the intraluminal transducer probe were examined, although the actual values were considerably higher (*Table III*). Using either system, however, the values obtained from occasion to occasion in any individual subject often varied considerably. The effect of this variation upon the reproducibility of the lower oesophageal sphincter pressure was assessed by correlating the values obtained from occasion to occasion in each individual. With the infusion system (*Fig.* 3) the reproducibility obtained from occasion to occasion on the same day was very satisfactory ($r = 0·88$), this being significant ($P < 0·01$). However, the correlation between the lower oesophageal sphincter pressure results measured on different days was not as good ($r = 0·74$), although this was still significant ($P < 0·05$). When the results from the intraluminal transducer system were evaluated (*Fig.* 4), although the reproducibility obtained from the two tests performed on the same day was significant ($P < 0·05$), the actual correlation ($r = 0·70$) was not as good as that obtained either from hour to hour or from day to day with the infusion

catheter system. Furthermore, there was no correlation at all between the lower oesophageal sphincter pressure measured from day to day with the intraluminal transducer system ($r = 0{\cdot}15$).

Recording side hole position
With tube 1, the mean l[illegible] sphincter pressure was 9·8 mm [illegible] With tube 2, the pressure w[illegible] s.d. 5·0, the difference between [illegible] of results being significant ($P<0{\cdot}001$). T[illegible] and 2 also enabled us to study the pressures in three different arcs of the circumference of the lower oesophageal sphincter (*Fig.* 6). It can be seen that in any one station pullthrough there was considerable variation between the results for the three pressure channel recordings in that test, and that this variation followed no particular pattern.

Discussion
The results of this study indicate that despite the advent of sophisticated electronic miniaturized pressure monitoring equipment such as intraluminal strain gauge transducers, the measurement of lower oesophageal sphincter pressure as recorded by the station pullthrough technique is more reproducible using a water-infused catheter system. In fact, the results we obtained with this latter, essentially simple, equipment were more reproducible from day to day than those obtained from hour to hour on the same day with the subminiature strain gauge transducers. This is very disappointing because the water-infused catheter system can be affected by a number of factors that influence recording fidelity (Dodds et al., 1976). One point worthy of emphasis is that our infusion catheter technique differed from the generally accepted standard technique as described by Stef et al. (1974) only in that we deliberately used a very low infusion rate of 27 ml/h for each pressure channel. Pope (1970) has confirmed that a slow infusion rate is satisfactory for examining the lower oesophageal sphincter.

Theoretically the intraluminal transducer probe (Sensotec EMP3) offers several advantages over the infusion catheter system. All the cumbersome plumbing is eliminated and since hydrostatic pressure effects no longer apply, the subjects can be tested in any convenient position (Dodds et al., 1976). However, the equipment required a long warm-up period, and as it was very temperature-sensitive, it had to be standardized at body temperature and not room temperature before use. It was very liable to baseline drift during the course of a recording session. Furthermore, the resultant traces showed a lot of superimposed high-frequency wave forms which made them much more difficult to interpret than those obtained from the infusion catheter system. This particular problem is one reason why the reproducibility of the station pullthrough with the intraluminal transducer probe was so poor. It may be that electronic filtering of this background noise would improve the quality of the recordings in the same way as the inherent damping of the infusion system probably does.

The fact that the intraluminal transducer probe recorded consistently higher pressures in the lower oesophageal sphincter than did the infusion system is not of any great importance. It is well recognized that dif[illegible]d differing pressures f[illegible]cter pressure (Earlam, [illegible] catheter system, we noted a differ[illegible] recorded both on the same d[illegible] in the individual subjects. [illegible]ngs of Perez-Avila and Irvin [illegible]y that there is a considerable [illegible]riation in the lower oesophageal sphincte[illegible]nal subjects. This is a finding which Pope (197[illegible]) has noted on many occasions. Despite this variation in sphincter pressure, however, we have demonstrated adequate reproducibility using an infused catheter system for measuring lower oesophageal sphincter pressure by the station pullthrough technique.

The second part of our study shows that the actual siting of the recording orifice in an infusion catheter system is important. The pressure is significantly higher when the side hole is situated more proximally than when it is located near the tip of the assembly. The reason for this difference is not clear. Suggestions that it is an artefact consequent upon angling of the tube against the lesser curvature of the stomach and thus the right side of the oesophageal sphincter cannot be correct. First, the catheter lumen distal to each of the recording side holes was occluded and therefore had no effect upon the pressures recorded. Secondly, the higher pressures were recorded by all three recording channels in tube 2 and thus were recorded from the circumference of the sphincter. We believe that the presence of a longer tail of infusion catheter lying in the gastric lumen below the recording holes may act as a stimulus to increase sphincter tone.

In the second part of the study we also noticed a considerable inter-transducer variation in the pressure recorded in any one test, in spite of the fact that all the recording orifices were arranged at the same level circumferentially, either at 5 or 15 cm from the tip. This variation confirms the presence of asymmetry of tone around the circumference of the sphincter, as previously noted by Kaye and Showalter (1971). In our study we have shown that the variation may be random. At first sight this may seem odd, but since our tube is quite soft and pliable (unlike that used by Kaye and Showalter), we have no reason to expect that it will have any constant radial orientation in respect to the sphincter.

We have thus demonstrated that there are two sources of inter-transducer variation in the station pullthrough technique—side hole position and radial asymmetry. An interplay of these two sources of variation may have had an effect on the results of our reproducibility study. The open-tube system, using as it did three radially orientated side holes, recorded three values from the circumference of the sphincter, which were averaged out and so the effects of radial asymmetry were negated. With the subminiature electronic probe, however, where the transducers all lay down the same side, the results would depend on the radial orientation of the probe.

Finally, as a sphincter is sensitive to distension, then the mere presence of a probe of any sort in its lumen must cause some stimulation. Therefore, any recorded pressures are not true resting pressures. The work of Kaye and Showalter (1974) and Lydon et al. (1975) on the effect of the catheter diameter on recorded pressures would support this argument.

[illegible] on [illegible] technique when [illegible] r [illegible] is used to measure lower [illegible] pressure. In normal subje[illegible] minor variation of sphincter ton[illegible] and from day to day. Differe[illegible] grossly differing results, and [illegible] attempted then the same syste[illegible] each case. The length of the cathe[illegible]ably projecting into the stomach below the re[illegible]ng orifices affects the recorded value for the lower oesophageal sphincter pressure. We would recommend that in oesophageal manometry the recording side holes should be situated as close to the tip of the catheter as possible. Radial asymmetry is a further cause of recorded pressure variation, but its effects are largely negated by using a multi-lumen catheter system which thus records around the circumference of the sphincter.

Finally, we feel that work should be directed towards finding a method whereby the function of the lower oesophageal sphincter, and any other sphincter, can be assessed without attempting to force a foreign body through its lumen.

recor[illegible]

The surgical management of [illegible] oesophagus and cardia: a revi[illegible] 292 patients treated over a 15-ye[illegible] -75)

J. W. JACKSON, D. K. C. COOPER, L. GUVEND[illegible] AND H. REECE-SMITH*

SUMMARY

Of 292 patients, excision of the tumour with replacement by stomach or jejunum was carried out in 216 in whom the lesion was considered operable on both technical and general grounds, intubation was performed in 45 and the remaining 31 were managed without operation.

Of the 216 in whom resection was performed, only 20 per cent were free from local spread, lymph node involvement or secondary deposits at the time of operation. Hospital mortality was 18 per cent and did not significantly differ between one 5-year period and another. Survival at 1 year was 54 per cent, at 2 years 25 per cent and at 5 years 14 per cent. The average length of survival following intubation was 2·6 months and following non-operative management 2·8 months. The poor average survival of between 3·5 and 5 months obtained in those patients with secondary deposits at the time of resection suggests that resection is of questionable value in this group.

There was a marked difference in survival following Roux loop procedures compared with upper partial gastrectomy for tumours of the lower third and cardia in patients without lymph node involvement or secondary deposits, strongly suggesting that upper partial gastrectomy, although a rather simpler and quicker operation, is not the operation of choice in these patients.

On 31 December 1976, after a minimum follow-up of 1 year, there were only 22 patients still alive of the original 292 (7·5 per cent).

DURING the 15-year period from 1 January 1961 to 30 December 1975, 292 patients with carcinoma of the oesophagus were admitted to Harefield Hospital under the care of one surgeon (J. W. J.). In many of these cases the tumour actually arose in the cardia of the stomach, but, as the presenting symptom (dysphagia) is frequently identical and as the surgical management is very similar, we have treated these two lesions as a single entity; indeed, in many cases it would be difficult, except possibly by histology, to localize the exact origin of the tumour. Throughout this period there was a consistent approach in the management of such patients. Operation involving excision of the tumour with replacement by stomach or jejunum was carried out whenever the lesion was considered operable on both technical and general grounds; 216 patients were thus treated. Of the remaining 76, 45 underwent some form of intubation procedure and 31 were managed without operation. Follow-up (to 31 December 1976) has been from 1 to 16 years.

Patients and methods

Patients

Sex incidence: Of the 292 patients seen, 169 were male (58 per cent) and 123 female (42 per cent), giving a male to female ratio of 1·4 : 1·0.

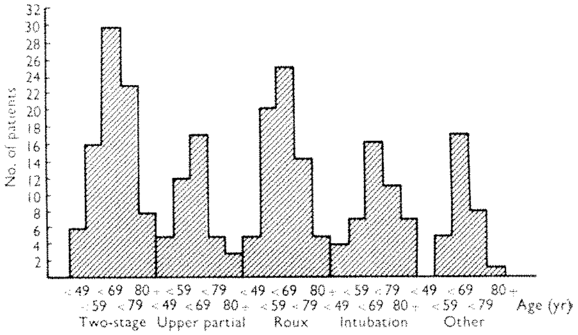

Fig. 1. Age of patient related to management.

Age incidence: The youngest patient seen was aged 27 years and the oldest 91 years with an average of 65 years. The greatest incidence was in the seventh decade of life (*Fig.* 1). The average age of the female patients (75 years) was considerably older than that of the male patients (58 years).

Presenting symptoms: In all but 30 patients (that is, in almost 90 per cent) the presenting symptom was dysphagia. Indigestion and loss of weight were other symptoms of importance. The duration of symptoms at the time when the patient was first seen at the hospital was from as short a period as 2 weeks to as long as 3 years (mean 22 weeks). There appeared to be no relation between the duration of symptoms and the operability of the lesion.

Site of tumour: No tumours of the cervical oesophagus were seen. It is customary to divide the thoracic oesophagus into three parts—upper (supra-aortic), middle (arch of aorta to inferior pulmonary vein) and lower (including the cardia of the stomach). Tumours of the lower third and cardia predominated (197 cases), though tumours of the middle third were also common (107 cases). Only 6 patients with a tumour confined to the upper third of the thoracic oesophagus were seen.

Tumours of the lower third and cardia were more common in men (125) than women (54) (male to female ratio of 2·5 : 1·0), whereas with tumours of the middle third the sex relationship was altered (men 41, women 66) (male to female ratio of 1·0 : 1·5). The relationship of the site and histology of the tumour to the sex of the patient can be seen in *Table I*.

Histology: The histology of the tumour was closely related to the site of origin (*Table I*). Squamous cell carcinoma predominated in the middle third of the oesophagus (87 of 107, 81 per cent), whereas adenocarcinoma was commonest in the lower third and cardia (116 of 179, 65 per cent). Twenty-four undifferentiated tumours were seen, fairly evenly distributed throughout the middle and lower oesophagus. One leiomyosarcoma occurred in the lower third and cardia, and in 3 cases the exact histological nature of the malignancy was not stated by the pathologist.

The number of patients seen during each of the three 5-year periods covered by the study (1961–5, 1966–70 and 1971–5) steadily increased from 68 during the first period, 102 during the second, to 122 during the third. Analysis of these patients reveals, however, that there was no statistical difference in the

sex ratio, duration or nature of symptoms, age distribution, site or histological incidence between one 5-year period and another.

Management
As dysphagia is such a distressing symptom, a fairly aggressive policy towards operative resection was followed. All patients were assessed initially with a barium swallow, oesophagoscopy and bronchoscopy. Only patients with a very advanced state of the disease where multiple secondaries were present or with extremely severe concomitant disease were excluded from operation on general grounds. Others were excluded on the grounds of technical inoperability where there was bronchial or tracheal involvement or evidence of direct local spread to other major organs such as the liver or lungs. In several cases the assessment of operability was finally made at laparotomy.

Intubation with a Celestin or Mousseau Barbin tube was performed in 45 patients with advanced disease. Four of these patients had been explored with a view to resection, which did not prove possible; in the remaining 41 patients intubation was a primary procedure. In 31 patients dilatation alone (8 cases), and/or radiotherapy (12 cases), together with palliative medical care, were the only measures considered applicable. In 10 of these patients exploratory surgery had been carried out initially and in 1 a temporary feeding gastrostomy was fashioned.

Of those patients in whom the tumour was considered resectable on both technical and general grounds, 1 patient with a tumour of the upper third of the oesophagus underwent a three-stage oesophagectomy with replacement by stomach, the oesophagogastric anastomosis being performed in the neck.

Eighty-three patients with a middle third tumour underwent a two-stage oesophagectomy with replacement by stomach, the anastomosis being performed through a right thoracotomy.

Patients with tumours of the lower third and cardia underwent a one-stage oesophagectomy through a left thoraco-abdominal incision when either a partial oesophagectomy and upper partial gastrectomy with oesophagogastric anastomosis was performed (63 patients) or a partial oesophagectomy and total gastrectomy with replacement with Roux-en-Y loop of jejunum was carried out (69 patients). The decision to perform an upper partial gastrectomy rather than a total gastrectomy was based on a number of factors, the most important of which was the presence or absence of tumour in the abdominal oesophagus or cardia. In cases where the tumour did not involve these regions an upper partial gastrectomy was performed. If the oesophagogastric junction or cardia was involved, a total gastrectomy was considered essential.

All anastomoses were performed using two layers of interrupted linen thread sutures.

The percentage of patients in whom resection procedures were performed varied little from one 5-year period to another, being 78 per cent (53 of 68) during 1961–5, 70 per cent (72 of 102) during 1966–70, and 75 per cent (91 of 122) during 1971–5. The resectability rate was identical in men and women (74 per cent).

Op., operation; T.-s. O., two-stage oesophagectomy; U.P.G., upper partial gastrectomy; R.L. Roux loop; Int., intubation.
* In 2 further cases the extent of spread was not stated.
† One further patient underwent a three-stage oesophagectomy (no local spread).

Extent of disease at time of operation
Whether resection of the tumour was considered to be curative or palliative was of little importance, for whenever dysphagia was present, resection, where possible, was considered the treatment of choice; in any case, evidence as to whether the operation was likely to be curative or not was frequently not available until the procedure was well advanced or even until resected tumour specimen had been studied under the microscope.

The extent of the disease at the time of resection is shown in *Table II*. Only 20 per cent of the total of 216 were free from local spread, lymph node involvement or secondary deposits at the time of operation. In 6 per cent local spread had occurred through the full thickness of the oesophagus, 67 per cent had lymph node involvement, and in a further 6 per cent macroscopic secondary deposits in such organs as the liver were already present.

Results

Hospital mortality
The operative mortality in these elderly patients, who were often grossly wasted as a result of their inability to take in adequate nourishment over a period of weeks or months, was high. Of those undergoing a two-stage oesophagectomy, the hospital mortality—those patients dying within 30 days of operation—was 20 per cent (17 of 83). After upper partial gastrectomy it was 19 per cent (12 of 63), and after a Roux-en-Y jejunal loop procedure, 14 per cent (10 of 69). The 1 patient undergoing a three-stage oesophagectomy recovered well and left hospital after 22 days. This gives an overall hospital mortality of 18 per cent (39 of 216).

Intubation [illegible] hospitalization as the more [illegible] resection.

Further procedures after resection

A proportion (30 per cent) of patients in all three operative groups required subsequent oesophagoscopy and dilatation. Thirty-three per cent of patients undergoing partial gastrectomy required oesophagoscopy and dilatation at some stage in their postoperative life, and the incidence following Roux loop procedures and two-stage oesophagectomy was 26 and 30 per cent respectively. In approximately two-thirds of these cases, dilatation was required to correct benign stricture formation at the site of anastomosis presenting as dysphagia and occurring early in the postoperative course (within a few weeks); this was generally easily managed by dilatation on one or two occasions. The other main indication for oesophagoscopy and dilatation was dysphagia resulting from local recurrence of tumour or from compression of the alimentary tract by enlarged infiltrated lymph nodes; dysphagia from these causes generally occurred later in the postoperative course and was frequently impossible to relieve, though dilatation, intubation and radiotherapy were each helpful on occasions.

Long term follow-up and survival

Of the original 292, 5 patients have been lost to follow-up. Four of these were patients in whom intubation had been performed and are therefore presumed to have died within a few weeks or months of the procedure. The fifth patient underwent a two-stage oesophagectomy. Follow-up (to 31 December 1976) has been from a minimum of 1 year to a maximum of 16 years.

Details of the percentage of patients still alive after each of the three types of procedure at 1, 2 and 5 years, excluding those dying in hospital postoperatively, are shown in *Table VIII*. The one patient subjected to a three-stage oesophagectomy survived for only 10 months. No patient in whom intubation was performed or who was managed by dilatation, radiotherapy, or other means survived for 1 year, the average length of survival for intubation being 2·6 months and for other forms of management 2·8 months.

If the numbers of patients surviving at 1, 2 and 5 years are considered as percentages of the overall number who *could* have survived as long, including those in whom resection was not performed, the survival curve, of course, drops even more sharply (*Fig*. 3). Survival at 1 year was only 32 per cent, at 2 years 15 per cent and at 5 years 5 per cent. Only 1 patient has to date survived for more than 10 years, a woman who is still alive and well almost 11 years after a two-stage oesophagectomy.

The percentage survival after resection and overall percentage survival are shown as actuarial curves in *Fig*. 3. There was no significant statistical difference between the 1-, 2- or 5-year survival for each of the

three resection procedures. The average survival in months after each of the resection procedures in relation to the extent of the disease at the time of operation is shown in *Table IX*. As would be expected the length of survival is directly related to the ex[illegible] of the malignant process at operation. There [illegible] statistically significant difference b[illegible] length of survival between or[illegible]ure and another. Average overa[illegible]wing resection in women was 16·6 [illegible] and in men 18·3 months.

There was no significant difference in the length of survival of patients who presented with symptoms that had been present for longer than 12 weeks (14 months) when compared with those whose symptoms had been present for 12 weeks or less (13 months).

There was a marked difference in the average length of survival in patients with no local spread or local spread but no lymph node involvement between either two-stage oesophagectomy or Roux-en-Y loop procedures, on the one hand, and upper partial gastrectomy on the other. This is particularly important in regard to comparison of survival between those patients undergoing Roux loop procedures and those undergoing upper partial gastrectomy, as both operations were performed for tumours of the lower third and cardia.

On 31 December 1976, at which date there was a minimum follow-up of 1 year, there were only 22 patients still alive out of the original 292 (7·5 per cent).

Discussion

The overall predominance of males to females in the ratio of 1·4 : 1·0 correlates fairly well with the figures of the Registrar-General for 1968 (male to female, 1·5 : 1·0) and of McKeown (1972) (male to female, 1·7 : 1·0). From our own centre, Mullard (1960) reported his experience of 140 patients with oesophageal and cardiac tumours seen in the period 1948 to 1958; only 40 were women giving a male to female sex ratio of 2·5 : 1·0, suggesting that in recent years there has been a change in the sex ratio in this disease in the region served by Harefield Hospital.

The preponderance of women to men in carcinoma of the middle third of the oesophagus is unusual; men predominate in most other published series (Miller, 1961).

The age incidence of the patients in the present series correlates well with other published series (Miller, 1961; McKeown, 1972); the maximum incidence was in the seventh decade of life. The women were, however, on average 16·5 years older than the men at the time of diagnosis and treatment. The resectability rate, however, was identical in both sexes, and the average length of survival following resection showed no significant difference between men and women. Although the disease affects women at a later age than men, it appears that the behaviour of the tumour is not significantly different.

The presenting symptom was dysphagia in almost 90 per cent of patients; investigation by barium swallow and oesophagoscopy should be carried out whenever a patient presents with this symptom. Our observation that the length of history does not appear to affect the length of survival of the patient agrees with that of Leverment and Milne (1974); it can only be assumed that most patients do not attend their doctor until such time as the dysphagia is critical. Al[illegible]viously t[illegible] longer in slow-[illegible] is likely t[illegible]hese tumours have [illegible]ar stage as the faster growing tumours in patients who present earlier.

The close correlation of squamous cell carcinoma with the middle third of the oesophagus and of adenocarcinoma with the lower third and cardia is illustrated in the pr[illegible]ies, though not so clearly as in that reported [illegible]er (1961).

The fact that at the time of resection, and after exclusion of several patients on the grounds of either technical or general inoperability, 80 per cent of the patients showed evidence of local spread of the tumour, lymph node involvement or even distant metastases illustrates the difficulty in obtaining good long term results in this disease. In the majority of patients the tumour is already very advanced at the time of presentation.

The overall hospital mortality rate following resection of 18 per cent falls in the middle of the range of mortality rates in reported series from various surgical centres in the world (McKeown, 1973); mortality rates of 4·9 per cent to 35·7 per cent have been reported following oesophageal resection. Obviously the mortality rate is related to the selection of patients for operation. In the present series, where a fairly aggressive policy was followed in an effort to alleviate the very distressing symptom of total dysphagia in many patients, a moderately high mortality rate must be anticipated in elderly patients with advanced disease.

It was Collis's impression (1971) that hospital mortality declines as the experience of the surgeon and his team increases, although his own results supporting this view are not statistically significant except with regard to improvement following his first 50 operations performed in the early 1950s when the mortality was 52 per cent. In the present series there was no significant difference in hospital mortality between one 5-year period and another.

The high mortality associated with intubation (31 per cent) is surprising as this procedure is regarded as a simple surgical operation, and the deaths mainly reflect the extremely debilitated state of the patients; intubation was only performed in those patients deemed unsuitable for resection. The mortality was as high in patients where intubation was carried out as a definitive primary procedure as in those where it was performed when resection was found impossible. A review of the literature confirms that any impression that intubation is a procedure accompanied by relatively low mortality is incorrect (Waddington and Bickford, 1961; Collis, 1971).

The reduction in the average number of days spent in hospital by those patients surviving after a resection operation or intubation from 27–30 days in the 1961–5 period to 16–19 days in the 1971–5 period is encouraging and brings a small ray of light to otherwise depressing results. It suggests that pre- and postoperative care have, in fact, improved during the 15 years covered by the study, but it does make the absence of improvement of the hospital mortality particularly disappointing. One would like to believe that with improved perioperative care, the mortality associated with oesophagectomy could be further reduced. A careful study of the percentage of patients undergoing operation, their age range and average age, the duration of their symptoms and the extent of the disease at the time of [illegible] to show any significant difference bet[illegible]d in the first 5-year period and those in e[illegible] two later 5-year periods; it therefore cannot be confirmed that the patients being selected for resection were less fit in the later periods than in the earlier, although it is possible that this still may be the case.

Although the numbers involved are [illegible]tively small, there is a greater risk of dying as a resu[illegible] resection operation if significant concurrent disease is present. The risk would appear to be less in upper partial gastrectomy than in two-stage oesophagectomy or Roux loop procedures, and possibly can be explained by the fact that upper partial gastrectomy is frequently a rather quicker and less stressful operation. In patients with existing pulmonary or cardiac disease it would therefore seem that, whenever possible, an upper partial gastrectomy might be preferred to a Roux loop procedure.

In the present series 5 hospital deaths were associated with anastomotic leaks and there were a further 3 non-fatal leaks (overall incidence of 3·7 per cent). This very low incidence of leakage at the site of anastomosis almost certainly resulted from the meticulous attention paid to this part of the procedure, both with regard to the maintenance of viability of the tissues and to the technique of anastomosis.

The two-layered technique, involving a relatively large number of interrupted linen-thread sutures, resulted in inversion of the tissues at the site of anastomosis and this may have been a factor in the moderately high incidence of patients requiring dilatation for benign stricture formation at some stage during the first few weeks after operation. Few patients, however, required dilatation on more than one occasion, and this complication was rarely a major problem.

The results of long term follow-up make depressing reading, with a 1-year mortality of 46 per cent even in those patients surviving resection. By 2 years 75 per cent of the patients who underwent successful resection were dead and by 5 years approximately 86 per cent had died.

Comparison of long term results is difficult as many reported series differ in important details and are not always strictly comparable, but the 5-year survival rate of 14 per cent following successful resection falls within the average of most published series, where survival rates of 3·8 to 23·5 per cent have been reported (Collis, 1971; McKeown, 1974). The 23·5 per cent 5-year survival obtained by McKeown (1974) is exceptional. Similarly, the 1- and 2-year survival figures of 54 and 25 per cent achieved in the present series are average for this disease (McKeown, 1974).

There appears to be little difference in the prognosis between those patients presenting with tumours of the middle third of the oesophagus and those presenting with tumours of the lower third and cardia. The percentage survival at 1, 2 and 5 years showed little difference and the overall average survival in months is again similar, although in both cases slightly better results were obtained with middle third tumours. However, the outlook is bleak with tumours at either site.

The various merits of upper partial gastrectomy with direct oesophagogastric anastomosis and total gastrectomy with Roux-en-Y jejunal replacement have been discussed fully by McKeown (1973). Total gastrectomy allows fuller block dissection of the regional lymph nodes, yet the preservation of the pyloric antrum for oesophagogastric anastomosis is more physiological and is surely an advantage if the long term survival of the patient were not adversely affected which, unfortunately, was not the case in the present series where there was a significant difference in the average length of survival in months following resection by upper partial gastrectomy when compared with the Roux loop procedure in those patients where there was no identifiable lymph node involvement or secondary deposits. Average survival was 12 months longer following a Roux loop procedure when the tumour had not spread locally and 20 months longer when local spread had occurred but regional lymph nodes remained uninvolved. This extended survival is very considerable when put in the context of the usual outcome of the disease and the overall results in this series.

The improved survival following Roux loop procedures in this small group of patients (37 patients in all—16 Roux and 21 upper partial gastrectomies) may be explained in a number of ways. Upper partial gastrectomy, being an operation that takes rather less time than a Roux loop procedure, may have been chosen in particularly elderly or debilitated patients in whom a reduction in operating time was preferable; this has not been the case in this series. As upper partial gastrectomy was performed only in those patients with tumours of the lower third of the oesophagus and not in those having involvement of the cardia and lesser curves, it could be assumed that lower third tumours must have a poorer prognosis than tumours of the cardia; this assumption is not generally accepted as being true and, in fact, the reverse is usually considered to be the case (McKeown, 1974). The most likely explanation of this improvement of survival is that a Roux loop procedure, involving the removal of a larger area of tissue and a larger number of the regional lymph nodes, is a more radical and therefore a more preferable cancer operation for tumours of this region.

The extremely short survival with an average of less than 3 months for patients managed by intubation and other methods of therapy illustrates the advanced nature of their disease and correlates well with other reports (Miller, 1961; Amman and Collis, 1971).

The poor average survival of between 3·5 and 5 months obtained in those patients with secondary deposits at the time of resection is little improvement on the survival rate following intubation, and this must make resection of questionable value in this group of patients, particularly if the tumour is sited at the lower end of the oesophagus or cardia. Resection undoubtedly led to a few weeks' improvement in swallowing, but when the morbidity and debility associated with such a major operation are considered, the effort by both patient and surgeon would hardly seem worth while. Possibly some form of bypass operation should be considered in these cases.

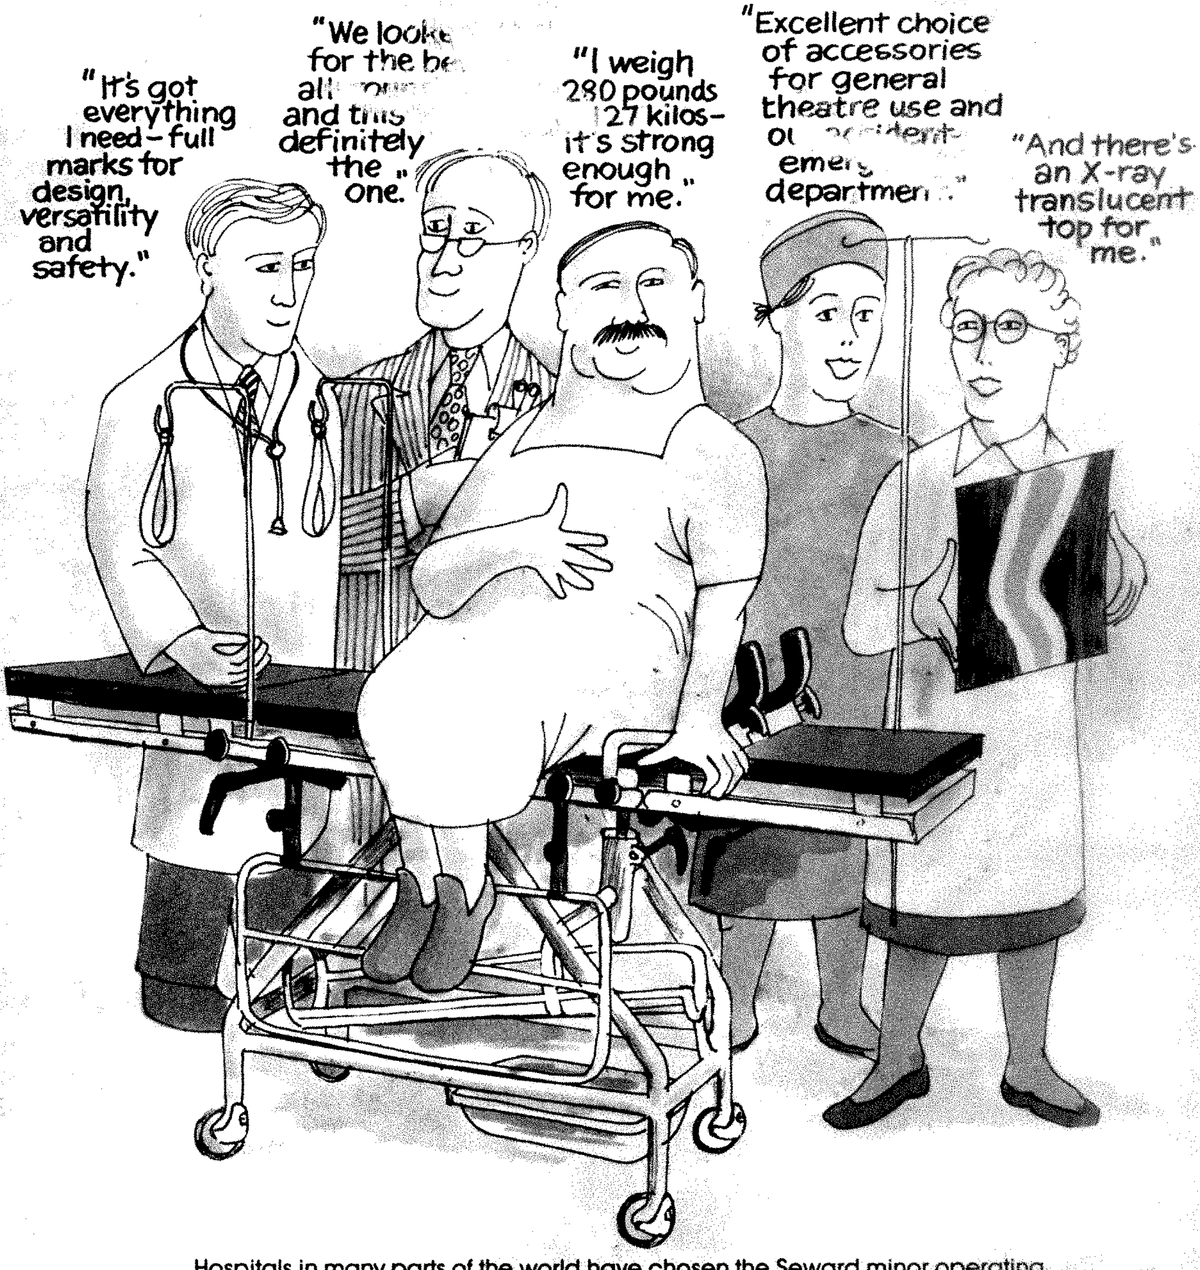
Conference on surgical tools and instruments

A one-day conference on surgical tools and instruments will be held at the University of Durham on Thursday 19 July 1979. There has been a massive increase in the development and use of prostheses in all aspects of surgery since the end of the Second World War; however, little attention has been drawn to the development of tools and instruments during this period. The aim of this conference is to present current work on the design, biomechanics and clinical use of tools and instruments employed in all aspects of surgery. Four sessions have been organized dealing with orthopaedic, abdominal, plastic and maxillofacial surgical instruments with an invited speaker presenting a key lecture in each session.

Papers are invited for inclusion at this conference; further details of the programme and abstract submission may be obtained from Dr R. J. Minns, Department of Engineering Science, University of Durham, Durham DH1 3LE.

Good reasons for choosing the Seward minor operating table



"It's got everything I need – full marks for design, versatility and safety."
"We looked for the best all-rounder and this definitely the one."
"I weigh 280 pounds 127 kilos – it's strong enough for me."
"Excellent choice of accessories for general theatre use and our accident emergency department."
"And there's an X-ray translucent top for me."

Hospitals in many parts of the world have chosen the Seward minor operating table. Because it has so many advantages — at a very competitive price . . .
Superb design quality — with stainless steel table-top and side rails.
Safety for the patient — instant tilt release into Trendelenberg and reverse Trendelenberg positions. Easily adjustable head and foot sections.
Accessories — wide range available from Seward.

Strong, handsomely styled, easy to keep clean. The ideal operating table for many surgical procedures, accident, casualty and outpatient departments. Send now for full details and a price list.

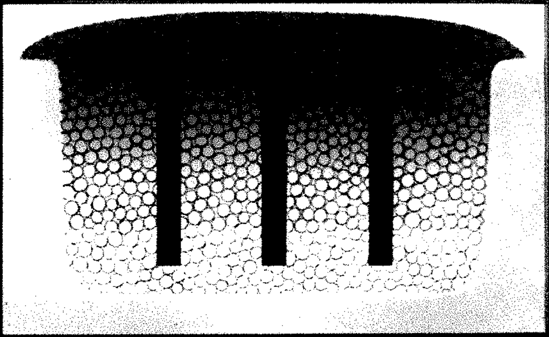
Creating the healing enviro

It's where a wound is continuously cleansed by thousands of individual beads; exudate is effectively absorbed faster than the wound's ability to secrete it.

It's where bacteria and wound debris are actively transported away from the wound.

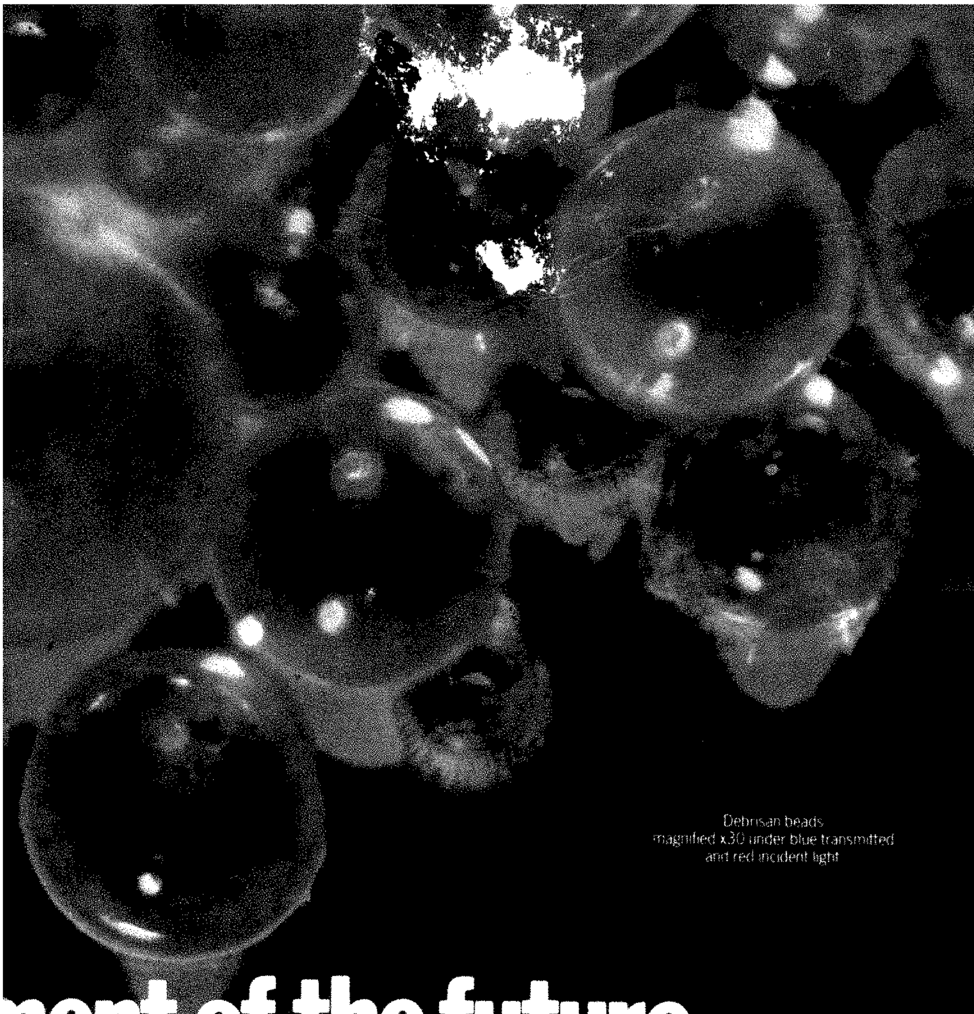
And substances responsible for inflammation, oedema and crust formation are separated from the delicate wound surface.

Debrisan beads create such an environment. Without any reported sensitization.



DEBRI

The totally new concept for cleansin



Debrisan beads

and red incident light

nent of the future.

By a unique mechanical action Debrisan removes from the wound those substances which normally complicate wound healing.

Pain and malodour are quickly reduced. Healing can now occur in an ideal environment. Fast. And often when all other approaches have failed.

Use Debrisan on all moist, small area burns, wounds and indolent ulcers whether clean or infected.

Patients can enjoy the benefits of the healing environment of the future. Today.

Debrisan (regd) dextranomer
is a product of
Pharmacia (Great Britain) Ltd
Prince Regent Road
Hounslow
Middlesex TW3 1NE
Telephone 01-572 7321
Further information is available
on request to the Company

Presentation
Sterile. Straw-coloured spherical beads of dextranomer of 0.1–0.3mm in diameter, packed in sterile castors containing 60g and sachets containing 4g.

Uses
Debrisan is a dressing for moist, small area burns, wounds and indolent ulcers whether clean or infected. Since it promotes the formation of granulation tissue it may be used to prepare burns for grafting.

Dosage and Administration
The wound must first be washed with saline and any loose debris removed. Moisture is left in the wound to ensure hydration of the Debrisan which is in direct contact with the wound surface. Debrisan is then poured onto the wound to a depth of 3mm. A piece of lint or Melolin is then bandaged over the dressing to hold the Debrisan in place. Before the layer is saturated – this is usually evident by discolouration of the whole layer – the Debrisan is rinsed off with saline and a new layer applied. Initially a twice daily change may be necessary, but after a few days, the frequency can often be reduced to once a day. Shallow wounds, or those in awkward positions, may be dressed more easily by mixing four parts of Debrisan with one part of glycerol to form a stiff paste. This may be spread into the wound with a spatula to a depth of 3mm or more. Dressing continues as above. The paste should be prepared freshly at each application.
Full instructions for use are enclosed with each pack. Treated in this manner the wound will remain soft and pliable during healing.

Contra-Indications, Warnings, etc.
1) Do not leave Debrisan for more than 24 hours on wounds with a very low exudation rate as it may dry and form a crust which may be difficult to wash off.
2) Occlusive dressings may lead to maceration of skin around the wound under treatment.
3) When deep infected wounds are treated, care must be taken to wash Debrisan from the depths of the wound.
4) No side-effects have been reported.

Warning
Debrisan spillage can render surfaces very slippery. Clear spillages promptly.

Caution
In order to avoid cross-contamination it is recommended that the contents of a castor or sachet be confined to the treatment of a single patient for one day.

Pharmaceutical Precautions
Keep in a dry place in well-closed containers.

Package Quantity
Castors of 60g. Also available in 4g sachets in packs of 7 sachets.

Basic N.H.S. Price:
60g castor £19.75
7 x 4g sachets £9.75
Product Licence No:
0009/0021

Chylothorax following resection of the oesophagus

K. H. LAM, S. T. K. LIM, JOHN WONG AND G. B. ONG*

SUMMARY

Chylothorax complicating operations on the oesophagus has been reported infrequently; it carries a mortality rate of about 50 per cent. A search of the literature has yielded only 10 cases. This paper reports 4 further cases which occurred among 685 resections of the oesophagus, giving an incidence of 0·6 per cent. The diagnosis should be confirmed with lymphangiography. Treatment should be early exploration and ligation in patients in whom the thoracic duct has been divided at operation. If the duct has been injured during blind dissection a period of conservative treatment is advisable. Parenteral nutrition is a useful adjunctive treatment.

SINCE its description by Bartolet in 1633 chylothorax has been reported as a complication of a large variety of operations. The incidence has risen in the past two decades because of the increase in the number of thoracic operations, and trauma from road accidents. Furthermore, increased awareness of the condition is also likely to contribute to the growing number of reports of this condition.

Although operations on the oesophagus have now been carried out for 60 years, it is surprising to note the low incidence of chylothorax resulting from damage to the thoracic duct. A search of the literature revealed only 10 cases. It is the purpose of this paper to review the literature, report 4 additional cases and discuss the problem of chylothorax in relation to operations on the oesophagus.

Review of the literature

Bressler et al. (1953) were the first to report chylothorax complicating oesophageal surgery (*Table I*). Their patient underwent oesophagectomy for carcinoma of the middle third through a left thoracotomy. The chylothorax which complicated the operation was treated with closed chest drainage and the patient survived. Since then there have been only 5 other reports of chylothorax following oesophageal resection (Brewer, 1955; Williams and Burford, 1964; Gingell, 1965; Roy et al., 1967; Rubin et al., 1977), and one reported series of 152 cases of carcinoma of oesophagus in which chylothorax was reported as a complication (Wu et al., 1955). Altogether 10 cases of chylothorax complicating oesophageal operations were collected from the literature. In only 8 cases was the method of treatment reported, and this included repeated aspiration in 2, chest drainage in 3, iodized talc insufflation in 1 and exploration with ligation of the duct in 2. The outcome of the patients was mentioned in 9 cases—3 succumbed and 6 survived.

Case reports

Since 1966 we have encountered 4 cases of chylothorax developing following oesophagectomy. Three of these cases were squamous cell carcinoma of the oesophagus, 2 at the middle third and 1 at the upper third. Oesophagectomy was performed in these patients. The fourth case was a squamous cell carcinoma of the piriform fossa for which pharyngolaryngo-oesophagectomy was [illegible]formed.

Between the years 1966 a[illegible]7 inclusive, 580 resections of the oesophagu[illegible]cinoma were performed and 105 pharyn[illegible]-oesophagectomies for cancer of the hyp[illegible]ynx or larynx. Therefore, the incidence of chylothorax complicating resection of cancer of the oesophagus was 0·5 per cent and that complicating pharyngolaryngo-oesophagectomy was 0·9 per cent. Altogether for all types of resection, the incidence was 0·6 per cent.

Case 1: B. S. M., a male aged 60, was admitted with a 3-month history of dysphagia. Investigations demonstrated a squamous cell carcinoma of the middle third of the oesophagus. As the patient could not swallow and was emaciated a feeding gastrostomy was created. Three weeks later oesophagectomy was performed through a right thoracotomy approach and, as postoperative radiotherapy was planned, no reconstruction was carried out at this stage. A segment of the thoracic duct adjacent to the tumour was resected (which was our usual practice) and the ends ligated with thread. The cervical oesophagus was brought out as an oesophagostome. The cardia of the stomach was closed with catgut and returned to the abdomen. For the first 5 days after the operation the patient was well and gastrostomy feeding with liquidized food was resumed. On day 6 a sudden gush of milky fluid issued from the right chest drain. A chylothorax was suspected and the presence of fat in the fluid was demonstrated with Sudan III stain. Exploration was performed through the previous right thoracotomy incision. Liquidized food was found leaking from the cardiac end of the stomach into the chest. The chest was closed and the abdomen opened. The cardia was trimmed and then closed with two layers of catgut suture. The amount of fluid draining from the right chest decreased for a few days but up to 1000 ml of milky fluid was again collected each day. The drainage fluid was again positive with Sudan III stain. Re-exploration was carried out through the right chest and extensive adhesions were found. The defect of the thoracic duct was identified alongside the azygos vein and was transfixed. There was extensive oozing from the raw surfaces and the patient went into shock postoperatively. Resuscitation was unsuccessful and the patient died 3 days later.

Case 2: L. H., a male aged 66, was admitted to our unit with carcinoma of the middle of the thoracic oesophagus. A Lewis–Tanner operation was performed. As in *Case* 1, a segment of thoracic duct was resected. Postoperatively the chest drain persistently yielded a large amount of milky fluid, up to 2000 ml per day. Chylothorax was confirmed when analysis of the fluid for total lipids showed that the level rose from 2·9 to 4·5 g/l in 2½ h after ingestion of 100 g of cream. Re-exploration was performed on day 6 and the site of chyle leakage identified and ligated. Although the amount of fluid draining from the right chest decreased, it had become purulent, and *Pseudomonas aeruginosa* was cultured from the fluid. The condition of the patient deteriorated and he died 8 days later.

Case 3: K. Y., a male aged 52, was admitted with hoarseness of voice and dysphagia. Endoscopy revealed a tumour arising from the right piriform fossa, extending into the larynx. Preoperative radiotherapy was given. Pharyngolaryngo-oesophagectomy was performed, during which the oesophagus was moblized blindly with the hand through an enlarged oesophageal

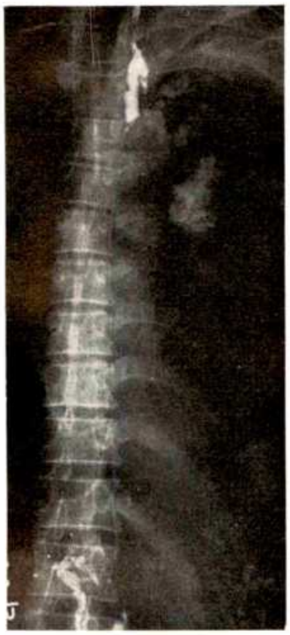

Fig. 2. *Case* 3. Lymphangiogram showing leakage of thoracic duct.

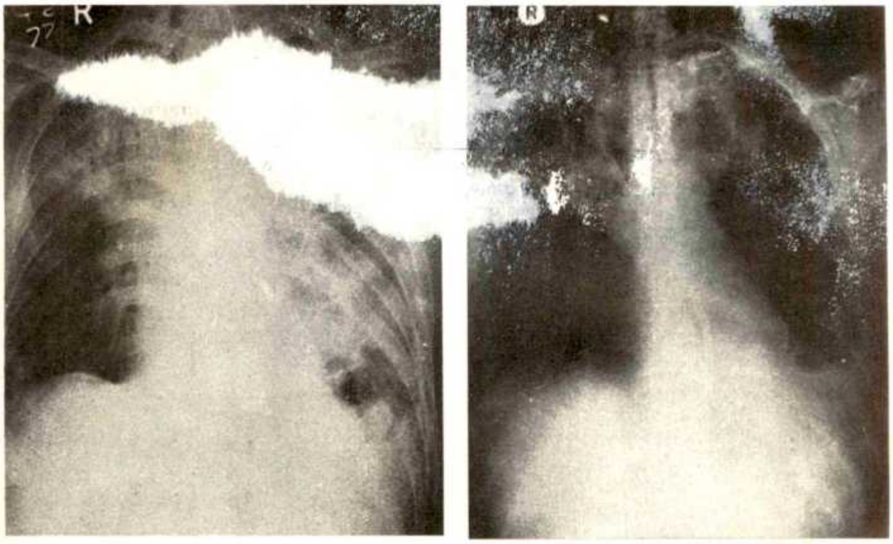
hiatus of the diaphragm. The mediastinal pleurae of both sides were opened during blind dissection and therefore chest drains were inserted. Postoperatively there was persistent drainage of more than 1000 ml of milky fluid from the left chest drain each day and chest X-ray showed persistent left pleural effusion (*Fig.* 1). Chylothorax was suspected and lymphangiography was performed (*Fig.* 2). Leakage from the upper segment of thoracic duct was demonstrated. As the drainage did not subside, on day 10 a right thoracotomy was performed and the thoracic duct identified and ligated. The chylous leakage was controlled. However, the patient developed bronchopneumonia and pulmonary oedema, resulting in death 1 week later.

Case 4: L. K. T., a male aged 57, was admitted with a 4-month history of dysphagia. Investigation showed a poorly differentiated squamous carcinoma of the oesophagus, at a level of 20 cm from the upper incisor teeth.



a *b*

Fig. 3. *Case* 4. Serial chest X-rays showing development of chylous collection. *a*, Day 5, mediastinal shadow well formed in the upper mediastinum. *b*, Day 6, mediastinal shadow decreasing in size after discharge of chyle.

A course of preoperative radiotherapy was given. Subsequently oesophagectomy was performed using the split sternum approach. The tumour-bearing part of the oesophagus was approached above the aortic arch, while the distal segment was freed by blind blunt dissection. For reconstruction the mobilized stomach was delivered to the neck through the posterior mediastinum and anastomosed to the cervical oesophagus. Postoperatively the patient was well. Only small amounts of fluid were drained from the chest. Daily chest X-ray showed a large opacity appearing gradually at the superior mediastinum (*Fig.* 3). This was subsequently shown to be a collection of chyle.

On the fifth postoperative day serous fluid discharged from the neck wound, and on the next day 1 litre of milky pleural fluid discharged from the left chest drain. Test with Sudan III stain showed the presence of lipid. A chylothorax was suspected. Lymphangiography was performed, confirming that the thoracic duct was draining into this collection of chyle at the superior mediastinum (*Fig.* 4). Parenteral nutrition was commenced because the excessive chest drainage amounted to 1000–2000 ml per day. Seven days after the onset of chylothorax the drainage gradually decreased. A repeat lymphangiogram showed no further extravasation. Parenteral feeding was maintained for another week before oral feeding was commenced. Apart from an infected sternal wound there was no other complication. The patient was discharged well after 3 months.

Discussion

The thoracic duct is in close relation with the oesophagus along most of its course, particularly in the thorax. It crosses from the right to the left side at the 5th or 6th thoracic vertebra (Van Pernis, 1949). Thus, when the lower thoracic segment is injured, chyle leaks into the right pleural cavity, whereas when the upper segment is damaged a chylothorax occurs on the left side (Ross, 1961). For carcinoma of the middle oesophagus our usual approach for oesophagectomy is through the right chest. A segment of thoracic duct near the tumour was routinely removed and the divided ends ligated with non-absorbable sutures. In *Cases* 1 and 2 the chylothorax probably resulted from slipping of the lower ligatures so that chyle drained into the right chest. During pharyngolaryngo-oesophagectomy for carcinoma of the piriform fossa (*Case* 3) and oesophagectomy via the split sternum approach (*Case* 4) the whole or part of the oesophagus was dissected blindly. Considering the proximity of the thoracic duct to the oesophagus and the frailness

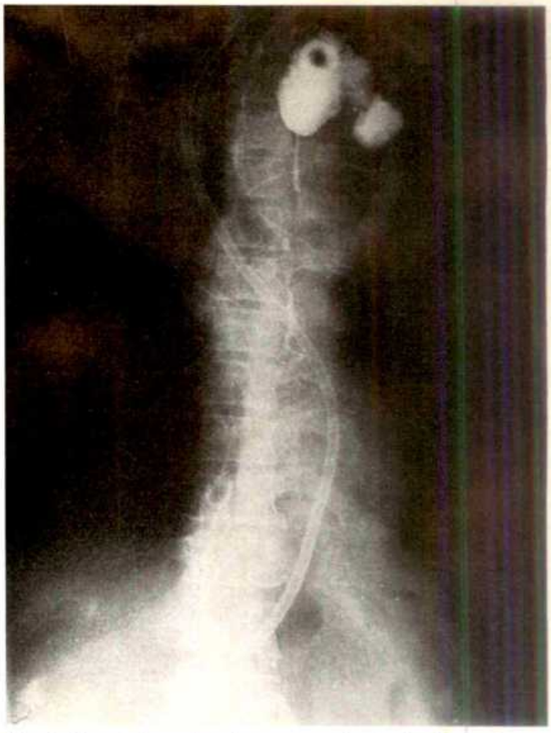


Fig. 4. *Case* 4. Lymphangiogram confirming leakage of thoracic duct into mediastinum.

of this and other nearby lymphatic channels it is surprising that chylothorax did not occur more often. In both these cases the upper part of the thoracic duct was damaged, thereby resulting in left-sided chylothorax.

Diagnosis of chylothorax is usually suspected when a large milky pleural effusion d[illegible] support for, but not confirmation of, [illegible] may be obtained with the detection [illegible] the fluid, or a characteristic [illegible] (Seriff et al., 1977), or the prese[illegible] in pleural fluid when fed orally (K[illegible] and Berry, 1954; Kjeldsen and Struve-Christensen, 1974). Roy et al. (1967) have emphasized that not all milky effusions are sequelae of thoracic duct fistulas. We also agree that these tests alone are not adequate for diagnosis of chylothorax, especially in patients who have undergone oesophagectomy, because of the complexity of the operative procedures involving various parts of the gastrointestinal tract. This is illustrated by *Case* 1, in whom fat-containing liquidized food leaked from the stomach. In another case of carcinoma of the oesophagus which we encountered, lipid-laden discharge issued via the right chest drain after oesophagectomy and stomach reconstruction. The diagnosis of chylothorax was shown to be erroneous when, at exploration, the thoracic duct was found to be intact and leakage from a perforated pyloromyotomy site was demonstrated. In both these cases, standard tests for lipid in the pleural fluid will be positive and any contrast medium given orally or by way of a nasogastric tube will also be recoverable through the chest drain.

Thus confirmation of the diagnosis of chylothorax complicating oesophageal surgery should be obtained by lymphangiography, the use of which has previously been described (Heilman and Collins, 1963; Nusbaum et al., 1964; Chavez and Conn, 1966; Carniel et al., 1971; Diaconis et al., 1976). This was performed in *Cases* 3 and 4. Lymphangiography not only established the diagnosis, but the site and degree of extravasation were also demonstrable. In addition, repeating the investigation allowed assessment of the progress and assisted in the decision to persevere with conservative treatment (*Case* 4).

The presence of a latent period before appearance of chylous pleural effusion (Garamella, 1958; Steiger et al., 1960; Ross, 1961; Tandon, 1968; Higgins and Mulder, 1971) is illustrated in *Case* 4. The delay is because of intact mediastinal pleurae holding the chyle in the mediastinum for the initial 3–5 days. On occasions when the amount of chyle is great it gives rise to a large mediastinal shadow before finally rupturing into the pleural cavity. Such an occurrence was mentioned by Bressler et al. (1953) and by Thorne (1958) and emphasized by Higgins and Mulder (1970). However, no chylous collection will develop if the mediastinal pleura has been damaged during operation, as in oesophagectomy via a thoracotomy incision (*Cases* 1 and 2), or if the pleura has been torn during blind dissection of the oesophagus (*Case* 3).

Goorwitch (1955) has presented a comprehensive review of the trend of treatment of chylothorax from a variety of causes. In 1948 Lampson reported the first successful case of transthoracic ligation of the thoracic duct. Before that time the treatment of chylothorax consisted of thoracocentesis, catheter drainage, rib resection, cervical ligation and phrenic nerve crushing, with a mortality rate of 45 per cent. Since Lampson's review, Goorwitch had collected 31 cases, of which 15 were treated with ligation of the duct with no mortality. He concluded that when chylothorax persisted despite adequate thoracocentesis or closed drainage, the thoracic duct should be ligated before the condition of the patient began to deteriorate. Later reports, however, have advocated non-operative treatment. Schmidt (1959) advised conservative therapy because of better prognosis; Maloney and Spencer (1956) advised trial of conservative measures for at least 3–4 weeks before considering surgery; Williams and Burford (1964) concluded that surgical intervention is rarely indicated; Selle et al. (1971) reviewed the indications for surgery in chylothorax and recommended ligation of the thoracic duct when there is daily loss of more than 1500 ml and when this is likely to last more than 14 days.

When chylothorax results from operations on the oesophagus we agree with the principle advanced by Selle et al. (1971). However, the mechanism of injury has to be taken into account in the selection of cases for operative or conservative treatment. The success of conservative treatment depends on collateral channels opening up, as demonstrated clearly by Chavez and Conn in dogs (1966). When oesophagectomy is performed for middle or lower third tumour through a right or left thoracotomy, the whole posterior mediastinum is usually dissected clean (*Cases* 1 and 2), so that it is unlikely that sufficient collaterals are left behind to provide drainage of abdominal chyle. A much longer time is needed before more distant channels will open up. Therefore, early operative intervention with religation of the duct should be the treatment of choice. On the other hand, when the oesophagus is mobilized by transabdominal finger dissection close to its wall, adequate collateral lymphatic channels are probably still present which may open up readily. In these cases it is worth while to attempt conservative treatment for a period, if the condition of the patient permits, before resorting to operative intervention. In *Cases* 3 and 4, the thoracic duct was damaged in this manner. *Case* 3 required ligation of the duct when drainage alone failed and *Case* 4 recovered with intercostal drainage alone.

Various other methods have been described for the treatment of chylothorax. Of interest is the method of induction of pleurodesis with iodized talc (Gingell, 1965). Among the three successfully treated cases reported by Gingell (1965), one patient had developed chylothorax following oesophagectomy for carcinoma of the lower third. This method may be employed if operation is contraindicated. Anastomosis of the thoracic duct to the azygos or hemiazygos vein (Brewer, 1955) seems unnecessarily complicated when ligation would suffice.

Identification at exploration of the site of chylous leakage usually presents no difficulty. However, many methods have been described which assist localization of the site of injury of the duct. These included preoperative administration of cream (Schmidt 1959), nasogastric instillation of methylene blue at operation (Engevik, 1976), subcutaneous injection of normal saline to increase the flow of chyle (Steiger et al., 1960), subcutaneous injection of Evans blue (Merrill, 1955) and filling the thorax with saline during operation to facilitate detection of milky chyle (Elliot, 1954). These may be attempted if difficulty is encountered at exploration.

A useful adjunct in the conservative management of patients with chylothorax is the use of medium chain triglycerides (Lichter et al., 1968; Tamir et al., 1968). The flow of chyle along the thoracic duct can be decreased since these triglycerides are absorbed directly into the bloodstream and do not enter the lymphatic system (Hashim et al., 1964). It is more effective to stop oral feeding completely and commence total parenteral nutrition (Birt and Connolly, 1952). The use of this method undoubtedly contributed to the success of *Case* 4 reported in this paper.

The mortality of chylothorax complicating oesophageal operations is high (*Table I*). Altogether 6 cases out of 13 with known outcome have died, giving a mortality rate of about 50 per cent. The high rate probably represents complications superadded to an operation which itself carries a mortality rate of 20–30 per cent.

Complications associated with [illegible] e use of the Celestin tube for benign oesophageal obstruction

M. B. RANSON AND H. T. JOHN*

SUMMARY

Two cases are described [illegible] of a Celestin tube took place [illegible] lodged in a benign oesophageal stricture for 14 months. One patient presented with apparent acute pancreatitis and the other with a minor gastrointestinal bleed.

Case reports

Case 1: A 76-year-old female with a 6-month history of dysphagia and regurgitation was shown at barium swallow examination and oesophagoscopy to have an endoscopically impassable stricture at 25 cm which appeared benign and from which brushings and biopsies were negative for malignant cells. The barium swallow showed a large sliding hiatus hernia with oesophagogastric reflux. On physical examination, however, a lump in the right breast was discovered which proved to be a carcinoma. Subsequently, in March 1976, she had a right mastectomy and a Celestin tube (Celestin, 1959) was inserted in the oesophagus through a high gastrotomy (Das and John, 1973). A large lymph node at the hiatus was removed, and on histology this proved to be inflammatory.

At a follow-up visit 11 months later she complained of some dysphagia and was seen to have an incisional hernia. Barium swallow examination was repeated and showed a patent, correctly positioned tube but with a bolus of food above it. The patient was recommended to drink aerated fluids. Four months later she was admitted as an emergency complaining of epigastric pain and she had fainted following the passage of a small melaena stool. Oesophagoscopy showed that the upper end of the tube was at 25 cm and there was free regurgitation of gastric contents. However, a barium swallow examination showed that the tube was blocked distally and the barium was seen to trickle down the sides (*Fig.* 1). An abdominal radiograph taken at the same time showed a radio-opaque marker in the right iliac fossa (*Fig.* 2). At operation the upper part of the tube was first removed with the rigid oesophagoscope and then the lower part was extracted after opening the caecum at laparotomy. The nylon spiral joining the two was cut (*Fig.* 3, note the plum stone also seen within the tube in *Fig.* 1). Both the hiatus and incisional hernias were repaired and 3 months later the patient was well and gaining weight, with no dysphagia and a sound scar.

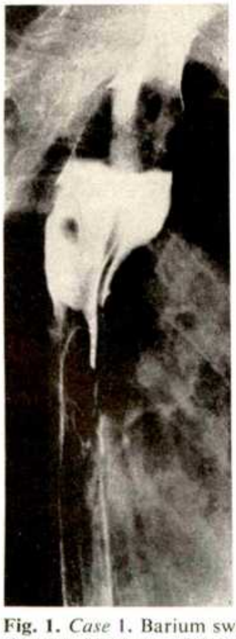

Fig. 1. *Case* 1. Barium swallow showing blockage of the Celestin tube in part by a plum stone

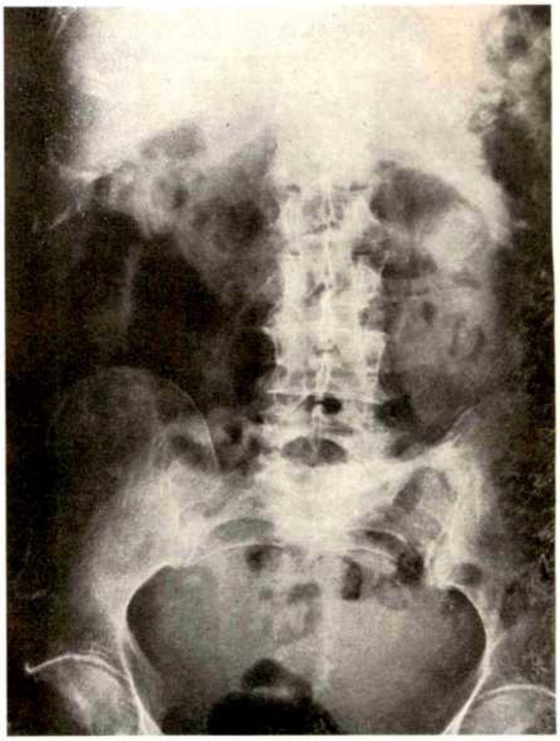

Fig. 2 *Case* 1. Abdominal radiograph showing the Celestin tube marker in the right iliac fossa.

Case 2: A 74-year-old female presented with a 3-year history of increasing weight loss and regurgitation of food. A barium swallow examination suggested late onset achalasia, but at oesophagoscopy a stricture was revealed at 40 cm from which brushings and biopsies were negative for malignant cells. Following the insertion of a Celestin tube the patient remained well, gaining weight until 14 months later, when she presented as an emergency with a 4-week history of intermittent, then constant abdominal pain, nausea and vomiting. She did not complain of dysphagia. On examination there was some abdominal tenderness and investigation showed her serum amylase to be 8000 i.u./l (normal range 70–300). An abdominal radiograph showed the radio-opaque marker of her Celestin tube to be in two pieces (*Fig.* 4). Two weeks later, after the acute episode had passed, a further radiograph (*Fig.* 5) showed the two pieces to have changed position. At operation, the

funnel of the Celestin tube was at the oesophagogastric junction and the rest of the tube was in two pieces in the mid- and terminal ileum. There were dense adhesions of loops of ileum around the smaller piece suggesting that a perforation had occurred, perhaps accounting for the high serum amylase. The three pieces were attached to each other by two strands of nylon; all were removed (*Fig.* 6). The segment of ileum containing the lower portion of the tube was resected and the specimen showed histological evidence of a perforation. When seen 6 weeks later the patient was swallowing well with a sound scar.

Discussion

Structural deterioration of the nylon-latex Celestin tube when used in benign oesophageal stricture has been described previously (Mackenzie et al., 1976). These authors reported cases presenting with the complication at intervals of 2 and 3 years respectively. We, likewise, have not found the complication when the tube is used for palliation in neoplastic stricture, probably because in this group the remaining lifespan is short, few patients surviving as long as 14 months. On theoretical grounds at least the tube might be held rigidly in a lengthening adynamic tumour segment. With benign stricture constant movement may be responsible for the disintegration of the tube, for examination after removal shows the appearance of a fatigue fracture of the tube opposite the lower end of the stricture. It is suggested that where intubation for benign oesophageal stricture is considered in patients unfit or unsuitable for major procedures, the intubation should be temporary and the tube should be removed after an interval of 3–6 months and, if necessary, replaced at a later date.

Translocating the aberrant right subclavian artery in dysphagia lusoria

C. K. MOK, K. L. CHEUNG, S. M. KONG AND G. B. ONG*

SUMMARY

A case of dysphagia lusoria with unusual associated symptoms in an adult is presented. The condition was treated by division of the aberrant right subclavian artery at its origin through a median sternotomy and translocating the distal subclavian artery to the aortic arch with an interposition Dacron graft. All the reported techniques of dividing and transposing the aberrant right subclavian artery in dysphagia lusoria are reviewed and discussed.

THE anomalous origin of the right subclavian artery has long been recognized. The first case was described by Hunauld in 1735. In 1789 Bayford reported a 62-year-old woman who died of extreme emaciation from oesophageal obstruction by an aberrant right subclavian artery. He coined the term 'dysphagia lusoria' to describe the condition. Kommerell described the radiological findings in 1936. In 1946 Gross first successfully relieved the dysphagia in a 4-month-old infant by dividing the aberrant artery through a left thoracotomy. Although the operation has since been performed and recorded on a number of occasions in infants, there had been no report of this operation for the relief of symptoms in adults until 1960 (Morris, 1960). Division of the anomalous right subclavian artery through a thoracotomy became the standard operation for dysphagia lusoria. No serious impairment of blood supply to the right arm was seen following division of the aberrant artery. Division of the subclavian artery is not without complications (Webb and Burford, 1952), however: in adults, development of the subclavian steal syndrome is a real possibility (Pifarre et al., 1971). The first report on re-establishing the continuity of the right subclavian artery after operation for dysphagia lusoria was described by Bailey et al. in 1965. Following this, four new procedures for the treatment of dysphagia lusoria were described in the literature (Siderys, 1969; Pifarre et al., 1971; Shumacker et al., 1971; Orvald et al., 1972). The purpose of this communication is to describe a case of dysphagia lusoria with unusual symptoms treated by a revised technique of translocating the aberrant artery and to review the various reported surgical techniques of dividing and reconstituting the aberrant right subclavian artery in the treatment of dysphagia lusoria.

Case report

The patient was a 46-year-old Chinese housewife. She complained of progressive difficulty over 8 months in swallowing hard food, associated with pain. There was no problem with fluid or soft diet. Hard and large pieces of food, such as apple, would 'get stuck' just behind the manubrium sterni and produce pain. In the recent 2 months she also experienced numbness of the left upper extremity. This was aggravated by lifting the left arm and carrying weights.

On examination, she was found to be in good general health. The carotid pulses were strong and equal. There was diminished *left* radial pulse. The blood pressure was 120/80 mmHg in the right arm and only 100/70 mmHg in the *left* arm. A grade 3/6 pansystolic murmur was heard all over the precordium with maximal intensity at the lower left sternal border. No other abnormalities were detected.

The chest radiograph and electrocardiogram were normal. A barium swallow examination (*Fig.* 1) revealed an indentation of the oesophagus at the level of D3, suggestive of external compression by an aberrant right subclavian artery. A transfemoral arch-aortogram (*Fig.* 2) confirmed the presence of an aberrant right subclavian artery. Since its origin was obscured by the overlying vessels, the presence or absence of a Kommerell's diverticulum (Kommerell, 1936) could not be determined by the arteriogram. Oesophagoscopy revealed nothing abnormal. A tentative diagnosis of dysphagia lusoria was made and the patient came to operation on 1 November 1977.

Through a median sternotomy incision the aortic arch and its four branches were exposed. The aberrant right subclavian artery was dissected out at the posterior mediastinum on both sides of the oesophagus and encircling tapes were applied. Kommerell's aneurysmal diverticulum was not observed (Kommerell, 1936). With gentle forward traction of the oesophagus, the retro-oesophageal portion of the artery was dissected from the right posterior mediastinum to its origin. Dissection from its origin upwards was difficult because of the presence of the left common carotid and left subclavian arteries. With one vascular clamp at the origin and another just proximal to the origin of the right vertebral artery, the aberrant right subclavian artery was transected to the left of the oesophagus. The proximal stump was oversewn. The retro-oesophageal portion of the right subclavian artery was brought to the right posterior mediastinum. It was then anastomosed to the aortic arch, end to side, proximal to the right common carotid artery, by means of an interposition Dacron graft and use of a partial exclusion clamp on the aorta (*Fig.* 3*b*). An interposition Dacron graft was used because the right subclavian artery was not long enough to anastomose directly to the aorta. The wound was closed in layers with four peristernal wires and a small mediastinal tubal drain.

Postoperatively, both radial pulses were palpable and equal. The blood pressure in both the upper extremities was 120/80 mmHg. The systolic murmur was found to be unchanged. Two days after the operation the patient volunteered the information that all her difficulty and pain in swallowing had completely disappeared and so had the numbness of her left upper extremity. She made a complete and uneventful recovery and was discharged well 14 days after the operation. A postoperative barium swallow examination revealed normal filling of the oesophagus with disappearance of the indentation (*Fig.* 4).

Discussion

The aberrant right subclavian artery is the most frequently encountered anomaly of the aortic arch. In the reported anatomical studies (Holzapfel, 1899; Goldbloom, 1922; Anson, 1936) its incidence varies from 0·6 to 1·8 per cent. Despite its common occurrence, clinical manifestations are unusual, and when they occur, they are usually noted in the first 2 or 3 years of life.

The arteria lusoria usually arises from the aorta posteriorly, as the fourth branch from the arch immediately behind the point of origin of the left

subclavian artery. It passes around the left and posterior aspects of the trachea and the oesophagus before coming to lie in the usual position to serve as the right subclavian artery (*Fig.* 3*a*). It is frequently stated that the aberrant right subclavian artery may pass in front of the oesophagus instead of behind it, or even in front of the trachea. After carefully reviewing the literature, Stewart et al. (1964) concluded that the passage of an aberrant right subclavian artery in front of the trachea or between the trachea and oesophagus must be extremely rare, if it ever occurs.

Table I: SUMMARY OF THE PUBLISHED SURGICAL APPROACHES AND TECHNIQUES FOR DIVIDING AND RECONSTITUTING THE ABERRANT RIGHT SUBCLAVIAN ARTERY IN DYSPHAGIA LUSORIA

Author	Approach	Method of division	Method of restoring pulsatile flow
Bailey et al., 1965	Right thoracotomy	Aberrant artery is transected as far into the left chest as possible	Distal right subclavian artery is reimplanted into ascending aorta posterior to SVC
Siderys, 1969	Cervical incision and left thoracotomy	Through cervical incision aberrant artery is transected at level of right carotid artery. Proximal aberrant artery is resected at its origin through a left thoracotomy	Distal right subclavian artery is anastomosed end to side to right carotid artery through cervical incision
Pifarre et al., 1971	Left thoracotomy	Aberrant artery is dissected free all the way to right side of mediastinum and transected at its origin	Dacron graft is sutured to distal right subclavian artery at retro-oesophageal position Anterior mediastinum is dissected. Subclavian artery together with Dacron graft is brought to right side of oesophagus, trachea and SVC and anastomosed end to side to aortic arch
Shumacker et al., 1971	Median sternotomy	Aberrant artery is isolated and divided at its origin. Distal artery is withdrawn from retro-oesophageal position	Distal right subclavian artery is anastomosed end to side to right carotid artery
Orvald et al., 1972	Cervical incision	Aberrant artery is identified to the right and left of oesophagus. It is divided to right of oesophagus. Proximal vessel is removed from behind oesophagus and oversewn	Distal right subclavian artery is anastomosed end to side to right carotid artery

SVC, Superior vena cava.

It appears that the mechanism of obstruction is the result of the artery lying behind the oesophagus, which is relatively well fixed between the rigid vertebral column posteriorly and the comparatively rigid trachea anteriorly. It is not clear why it produces symptoms in only a minority of those individuals with this anomaly. Klinkhamer (1966) felt that the retro-oesophageal artery is of clinical importance when the right carotid artery arises abnormally far away to the left in such a manner as to trap the somewhat flexible trachea and oesophagus and to prevent their anterior displacement at the crossing of the retro-oesophageal vessel. This is not generally accepted, however (Shumacker et al., 1971), and was not observed in our case. The mechanisms involved in the onset or aggravation of symptoms are also not understood. When symptoms occur in an adult, atherosclerotic rigidity, tortuosity and dilatation of the artery are suspected as contributing factors (Lichter, 1963). It is important to be able to recognize this anomaly as a cause of dysphagia, as corrective surgery relieves the symptoms completely.

The clinical features and radiological characteristics are well described in previous reports. The present case is of special interest in that pain, numbness of the left upper extremity and diminished radial pulse and blood pressure in the left instead of the right arm have never previously been reported in association with dysphagia lusoria. In the literature the classic description is of diminished radial pulse and blood pressure in the right rather than in the left arm (Felson et al., 1950; Shumacker et al., 1971). In the present case, since the aberrant right subclavian artery arose almost immediately behind the origin of the left subclavian artery, it might have exerted some pressure effect and impeded blood flow to the left arm. The fact that the pain and numbness disappeared completely after corrective surgery indicates that the aberrant artery was responsible for these features.

Since Gross inaugurated surgical correction of the condition in 1946, simple division through a thoracotomy has become a standard operative procedure for dysphagia lusoria. Gangrene of the upper extremity has been reported following ligation of the subclavian artery (Webb and Burford, 1952) and subclavian steal syndrome has also been described following simple division of the aberrant right subclavian artery (Pifarre et al., 1971). It would certainly seem wise to re-establish the arterial continuity in order to prevent these disabling complications.

The aberrant artery has been successfully divided and reconstituted by five different approaches and techniques (*Table I*). There is no doubt that Gross' original proposal of a left thoracotomy approach provides the best exposure of the aberrant artery at its origin. However, transposing the aberrant artery to the proximal aortic arch after division through a left thoracotomy, as suggested by Pifarre et al. (1971), is by no means a simple procedure. It involves bringing the aberrant artery from the posterior to the anterior mediastinum and two 'artery-to-graft' anastomoses deep in the mediastinum. It might be difficult to control the haemorrhage should there be bleeding from the anastomoses or slipping of the vascular clamps. Technically, it is possible to transect the aberrant artery through a right thoracotomy and reimplant the distal subclavian artery to the ascending aorta (Bailey et al., 1965). With this approach, however, a larger proximal stump than desired may be left behind. A patient with residual symptoms of dysphagia following this procedure has been reported (Pifarre et al., 1971). Besides, if bleeding occurs at the proximal stump, it will be very difficult to control it through the right thoracotomy.

Orvald et al. (1972) demonstrated that the aberrant artery could be divided and transposed through a single cervical incision. With this approach, however, the operative field is confined to the base of the neck and the thoracic inlet, and it would not be easy to control the aberrant artery at its origin should intraoperative haemorrhage occur. Siderys' combined cervical and left thoracotomy approach (Siderys,

1969) is a safer procedure, but it involves two separate incisions and positioning of the patient twice.

Since intraoperative haemorrhage and damage to the adjacent nerves and thoracic duct are the possible hazards of operating in this area, the ideal approach to the aberrant artery will be an incision that provides good exposure and full control of the aberrant artery during dissection, division and anastomosis. We find that the mediastinal approach through a median sternotomy incision, as utilized by Shumacker et al. (1971), satisfies these criteria. Early on in the operation the aberrant artery should be taped at its origin and to the right of the oesophagus. With gentle forward retraction of the oesophagus the dissection of the retro-oesophageal portion of the artery should be started from the right posterior mediastinum towards its point of origin from the aortic arch. The first portion of the aberrant artery is almost completely covered by the left carotid and left subclavian arteries. The aberrant artery should be divided to the left of the oesophagus with vascular clamps applied to the origin and just proximal to the origin of the right vertebral artery respectively.

By anastomosing the distal right subclavian artery to the right carotid artery it appears that the 'normal' anatomy is restored. There is, however, the possibility of some decrease in the blood supply to the right carotid artery, and, furthermore, in performing the end-to-side anastomosis, the partial exclusion clamp might cause transient cerebral ischaemia and damage to an atherosclerotic right carotid artery. We therefore feel that a better way of restoring pulsatile flow to the right subclavian artery is to anastomose the artery to the aortic arch with or without an interposition Dacron graft.

In our opinion, the operation of choice in dysphagia lusoria is to divide the aberrant artery at its origin through a median sternotomy and transpose the distal subclavian artery to the proximal aortic arch with or without an interposition Dacron graft.

Haemoccult

Greater accuracy in the detection of bleeding from the lower G.I. tract.

Haemoccult is an occult blood test based upon the reaction between guaiac impregnated filter paper, altered blood in faeces and developer solution containing stabilised hydrogen peroxide.

Haemoccult is supplied in Laboratory packs containing 50 test envelopes, applicators and developer solution. Basic NHS cost £13·25.
Haemocult is also supplied in Patient packs containing 50 bags of three test envelopes, applicators and developer solution.
Basic NHS cost £39·75.
Basic NHS cost of 1 patient bag 79½p.

Haemoccult is a simple and efficient 30 second test to detect the presence of occult blood in faeces.
This test, as modified by Greegor, has shown a remarkably low incidence of false-positives.*

Gastric carcinoma and previous peptic ulceration

D. J. ELLIS, R. D. KINGSTON, V. S. BROOKES AND J. A. H. WATERHOUSE*

SUMMARY

The incidence of patients with gastric carcinoma having had a previously diagnosed or suspected peptic ulcer was noted in two studies. These studies were the West Midlands Gastric Chemotherapy Trial (1974–6) and a retrospective study of patients presenting to the United Birmingham Hospitals with gastric carcinoma during the years 1958–62 and 1968–72.

The incidence of patients found to have had a previous operation for duodenal ulcer or to have post-mortem evidence of one was 6·5 per cent and 5·7 per cent respectively. A radiologically proved duodenal ulcer had been identified in 5·5 per cent and 2·1 per cent respectively and the incidence of previous symptoms suggestive of a duodenal ulcer was 4·0 per cent and 5·2 per cent. These figures indicate the total incidence could be 12·97–16·0 per cent, which is much higher than previously reported.

The mean time interval between operation for duodenal ulcer and the development of gastric carcinoma was much longer in patients having had a partial gastrectomy than in patients having had a vagotomy and drainage procedure.

The incidence of previous benign gastric ulcers was 2·5 per cent and 0·9 per cent. Fifty-three per cent of patients having had a previous operation for duodenal ulceration were found to have an unresectable carcinoma, compared with the overall unresectable rate of 35 per cent.

THE relationship of chronic benign gastroduodenal conditions to gastric carcinoma has been studied by several authors (De Jode, 1961; Burns and Taubman, 1967; Stalsberg and Taksdal, 1971; Nicholls, 1974). Most of the information has come from retrospective surgical or post-mortem studies, with the result that those cases not treated surgically or not coming to post-mortem have been excluded.

In the course of a recent trial of cytotoxic chemotherapy for patients with unresectable gastric carcinoma in the West Midlands (Kingston et al., 1978), we noted an unusual number of patients with previously diagnosed or suspected peptic ulcer and in particular with duodenal ulcer. These cases were analysed in detail and subsequently a retrospective survey of a larger group of patients with gastric carcinoma was undertaken.

Patients and methods

The West Midlands Chemotherapy Trial (WMCT) involved 200 patients with unresectable gastric carcinoma. The retrospective survey was based on all patients with gastric carcinoma admitted to the United Birmingham Hospitals (UBH) over two separate periods, each of 5 years, a decade apart (1958–62 and 1968–72 inclusive). The separate periods were selected because vagotomy and pyloroplasty had superseded partial gastrectomy as the operation of choice for duodenal ulcer in Birmingham in the early 1960s, and the two groups might therefore reflect differences in the relationship of a particular operation to subsequent carcinoma of the stomach.

In the 10 years studied the numbers of cases notified to the Birmingham Cancer Registry from the UBH were as follows: in 1958–62 410 cases were notified, of which full records were available in 386 (94 per cent); during 1968–72, 452 cases were notified, of which 440 ([illegible] per cent) had full records available; a total of 826 patients were thus studied in the UBH group.

In both the WMCT and the UBH groups the medical histories of the cases were reviewed and any patients with previous history of duodenal or gastric ulceration were divided into the following categories:

1. Previous surgery: (*a*) partial gastrectomy; (*b*) gastro-enterostomy; (*c*) vagotomy and drainage procedure; (*d*) simple suture of perforation.
2. Chronic peptic ulcer found at operation for gastric carcinoma or at post-mortem.
3. Previous barium meal evidence of a peptic ulcer.
4. Previous dyspeptic symptoms requiring medical treatment (at least 5 years before the diagnosis of gastric carcinoma).

All information was obtained from the hospital records and/or Cancer Registry records.

Results

The WMCT showed 13 patients to have had previous surgery for duodenal ulcer, 11 had had radiological evidence of duodenal ulcer and 8 had previous dyspeptic symptoms.

In the period 1958–62 there were 20 patients who had had a previous operation for duodenal ulcer. In addition, 2 patients had definite evidence of duodenal ulceration (i.e. chronic ulcer at operation for gastric carcinoma or at post-mortem). Seven patients had had previous radiological evidence of duodenal ulcer and 20 patients had previous dyspeptic symptoms requiring medical treatment.

In the period 1968–72 there were 22 patients who had had a previous operation for duodenal ulcer, and 3 patients had definite evidence of duodenal ulcer (i.e. chronic ulcer at operation for gastric carcinoma or at post-mortem). Ten patients had had radiological evidence of duodenal ulcer and 23 patients had previous dyspeptic symptoms.

The combined results are shown in *Table I*.

There does seem to be a marked difference in the time interval between patients developing cancer of the stomach after partial gastrectomy for duodenal ulcer and those who developed carcinoma after previous vagotomy and pyloroplasty for duodenal ulcer. *Table I* shows that in the UBH group the mean time interval between partial gastrectomy for duodenal ulcer and the development of gastric carcinoma was 24·2 years and in the WMCT it was 18·7 years. In patients who had previously undergone vagotomy and pyloroplasty for duodenal ulcer the mean time interval between that operation and the development of gastric carcinoma was 6 years in the UBH group and 5·4 years in the WMCT group.

In the two 5-year periods studied in the UBH group there was in fact no real difference between the numbers of patients undergoing partial gastrectomy for duodenal ulcer and those undergoing vagotomy and pyloroplasty.

Table II: STUDIES OF THE ASSOCIATION OF CHRONIC BENIGN GASTRODUODENAL CONDITIONS AND GASTRIC CARCINOMA

Centre	Reference	No. cases	Duodenal ulcers	Gastric ulcers
St James', London	Nicholls, 1974	1473	3 (0·20%)	14 (0·95%)
London Hospital, London	De Jode, 1961	1000	12 (1·20%)	6 (0·60%)
Lausanne, Switzerland	Saegesser and James, 1972	725	15 (2·06%)	3 (0·41%)
Oslo, Sweden	Stalsberg and Taksdal, 1971	500	3 (0·60%)	3 (0·60%)

Of the 826 patients of the UBH group, only 7, and of the WMCT group, only 5, patients had evidence of gastric ulcer, compared with the total of 60 cases of proved duodenal ulcer and 79 probable duodenal ulcers.

Discussion

Of the total of 1026 patients studied in the two groups, 55 (5·4 per cent) had previously had an operation for duodenal ulcer—a much higher incidence than has previously been reported (*Table II*). A further 33 patients (3·2 per cent of the total) had a duodenal ulcer confirmed at the time of operation for the carcinoma, at post-mortem or by previous radiological studies. The confirmed incidence of previous duodenal ulcer was therefore 8·6 per cent. In addition, 51 patients (5·0 per cent) had had a long history of dyspepsia typical of duodenal ulcer at least 5 years before the onset of symptoms referrable to the carcinoma. Since there was no absolute confirmation of the ulcer diagnosis in these cases, the validity of the last category may be open to question, but it is not unreasonable to conclude that the overall incidence is greater than that in the positively proved cases (8·6 per cent) above.

These figures give no indication of the number of people suffering from a duodenal ulcer who eventually develop gastric carcinoma. Nicholls (1974) attempted to define the number of patients who, in the long term, develop a gastric carcinoma following a partial gastrectomy for a duodenal ulcer. The figure reached was 1 in 865 patients. In his study follow-up was known not to be complete, and it relates only to partial gastrectomy, with no patients included who had not undergone surgery. In view of the difficulty in establishing a reliable figure for the incidence of duodenal ulcer in the general population, a long term general practice survey, including all patients with a proved duodenal ulcer, would be required to find the true total incidence of subsequent gastric carcinoma.

It is interesting to speculate as to the possible mechanism of how gastric carcinoma arises in patients who have or have had a duodenal ulcer. A relationship between chronic gastritis and gastric carcinoma has been shown to exist by several workers (Magnus, 1937; Strickland et al., 1970; Imai et al., 1971; Du Plessis, 1974) and carcinoma develops more commonly when cellular hyperplasia (Chusid et al., 1964) or metaplasia (Morson, 1955a, b) is present. Mucosal changes may be initiated by gastric stasis (Dragstedt and Woodward, 1963; Dragstedt, 1965), or bile reflux producing chronic gastritis (Lawson, 1964; Capper, 1967; Capper et al., 1967).

Gouch and Craven (1975) believe that there is sufficient clinical, pathological and experimental evidence to support the view that a gastrojejunal anastomosis is a premalignant condition. Lawson (1965) showed that in about 100 per cent of cases of a gastrojejunal anastomosis there was an associated chronic gastritis, but that gastritis was much less common after pyloroplasty or a Billroth I anastomosis.

It was noted in our studies that the mean time interval between surgery for a duodenal ulcer and the development of gastric carcinoma was much longer following a partial gastrectomy. The shortest interval for partial gastrectomy was 4 years and the longest 43 years, with a mean of 24 years, while the range for vagotomy and drainage was 2 to 18 years with a mean of 6 years. The significance of this finding in the small number of patients studied is limited, but if this was a true trend then it may be another indication for performing a partial gastrectomy for duodenal ulceration. It is possible that gastric atrophy leading to mucosal changes occurs more rapidly following vagotomy and drainage than partial gastrectomy. Further, it is generally recognized that 45 per cent of all gastric carcinomas arise at the pylorus and antrum; hence, removing this area and two-thirds of the stomach must be one important means of preventing a future carcinoma developing.

A significantly increased incidence of gastric carcinoma developing in the gastric stump following partial gastrectomy for gastric ulcer has been demonstrated (Nicholls, 1974). One in every 76 patients developed a carcinoma a minimum of 3 years after surgery. This is strikingly higher than the normal population incidence and strongly indicates a mucosal rather than an extrinsic factor such as diet as the cause.

Evidence would indicate that chronic gastritis is the premalignant condition common to the whole range of duodenal ulcer patients, i.e. non-operative and postoperative patients.

Our total incidence of previously diagnosed benign gastric ulcers was 1·17 per cent. This is higher than other reports (Fischer et al., 1947; De Jode, 1961; Stalsberg and Taksdal, 1971; Saegesser and James, 1972; Nicholls, 1974), which have only taken account of operations for gastric ulcer and not included radiologically diagnosed, medically treated ulcers.

This incidence relates very closely to the previously reported association between gastric ulcer and gastric carcinoma in the West Midlands (Brookes et al., 1965). In that series the incidence of proved gastric ulcer was only 1·5 per cent. This compares dramatically with the 8·6 per cent incidence of previous duodenal ulcer.

As described in other reports (Debray et al., 1958; Yanishevsky and Klimenkov, 1968; Nicholls, 1974), we noted the high number of patients with unresectable carcinoma in the group who had had previous surgery for a duodenal ulcer, 53 per cent of this group being unresectable compared with 35 per cent overall. This high unresectability rate is probably due to failure on the part of the clinician to suspect carcinoma in these patients. Other reports (Pygott and Shah, 1968; Graves and Herrington, 1971) have stressed the fact that any patient presenting with further dyspeptic symptoms more than 5 years after surgery for peptic ulcer should be suspected of having developed a gastric stump carcinoma and not a stomal ulcer, which tends to present within 5 years.

A reappraisal of the value of carcinoembryonic antigen in the management of patients with various neoplasms

M. J. COOPER, C. R. MACKIE, D. B. SKINNER AND A. R. MOOSSA*

SUMMARY

Eight hundred and eight patients with histologically proved malignant disease had carcinoembryonic antigen (CEA) estimations performed at the time of tissue diagnosis. An elevated level was found in 384 of 518 patients with gastrointestinal neoplasms (74 per cent) and in 162 of 290 patients with other neoplasms (56 per cent). No correlation was found between CEA elevations and tumour differentiation. There was a good correlation between tumour staging and CEA levels for patients with colorectal cancer; the more advanced the tumour, the higher the CEA.

Several illustrative cases are presented and the role of CEA assay in the diagnosis and management of neoplasia is discussed. CEA assay is a poor screening test for neoplastic disease, but serial CEA monitoring is valuable in the detection of residual or recurrent cancer.

CARCINOEMBRYONIC antigen (CEA) was first described by Gold and Freedman in 1965 and was hailed as a specific tumour marker for colonic cancer (Thompson et al., 1969; Nugent and Hansen, 1971). Further studies with this antigen have shown that levels are elevated in a large proportion of patients with a variety of malignant and benign diseases (Zamcheck et al., 1972; Martin et al., 1976). Its value in the diagnosis and management of neoplastic disease needs to be redefined. We have correlated the results of all CEA estimations over the past 5 years in patients with histologically proved malignant disease and have studied several cases serially to demonstrate the value of CEA estimation in prognosis and management.

Patients and methods

Between March 1972 and January 1978, CEA estimations were performed on sera from 808 patients with histologically proved malignant disease at the University of Chicago. All assays were performed by the Hansen Z-gel method (Hansen et al., 1971) (Hoffman–LaRoche Inc.), a normal value being less than 2·5 μg/l; all determinations were first performed by the indirect method and those sera with a value greater than 20 μg/l were re-evaluated by the direct method. The initial CEA levels were recorded within 6 weeks of a tissue diagnosis being obtained, and all values were correlated with the surgical pathology reports. In those patients with cancers of the gastrointestinal tract note was taken of the histological differentiation; and for colonic cancers the staging was recorded by the revised Dukes' method of Astler and Coller (1954).

Results

A CEA level was obtained for 290 patients with a variety of non-gastrointestinal neoplasms; 56 per cent of this group had a CEA greater than 2·5 μg/l at the time of tissue diagnosis, and 60 per cent produced an elevated CEA at some time (*Table I*). There was a total of 526 gastrointestinal neoplasms; an elevated CEA was produced by 76 per cent of the adenocarcinomas, 60 per cent of the squamous carcinomas and 75 per cent of the APUD tumors (*Table II*). The CEA level in patients with various gastrointestinal neoplasms was compared with cellular differentiation (*Fig.* 1); no correlation could be found. In patients with colorectal cancer, the most advanced tumours as determined by the modified Dukes' classification gave rise to the highest percentage of elevated CEA levels (*Fig.* 2).

Table I: RESULTS OF CEA ASSAYS ON PATIENTS WITH NON-GASTROINTESTINAL NEOPLASMS

Primary neoplasm	No. of patients	CEA > 2·5 μg/l: At time of tissue diagnosis (%)	CEA > 2·5 μg/l: At any time (%)
Lung	54	66·7	72·2
Breast	54	68·5	72·2
Kidney	9	66·7	66·7
Hodgkin's disease	18	22·2	27·8
Prostate	21	66·7	71·4
Testis	2	50	50
Gynaecological (misc.)	18	66·7	66·7
Thyroid	4	50	50
Bladder	10	60	60
Lymphoma (non-Hodgkin)	32	15·6	18·8
Sarcoma (misc.)	5	0	20
Skin (misc.)	10	30	40
Total	290	55·9	60·3

Table II: RESULTS OF CEA ASSAYS ON PATIENTS WITH GASTROINTESTINAL NEOPLASMS

Primary neoplasm	No. of patients	CEA > 2·5 μg/l: At time of tissue diagnosis (%)	CEA > 2·5 μg/l: At any time (%)
Oropharynx (squamous)	39	58·8	58·8
Oesophagus (squamous)	18	61·6	66·7
Stomach (adeno)	69	59·4	78·3
Cholangiocarcinoma	11	72·7	100
Hepatoma	12	75	75
Pancreas (adeno)	77	80·5	89·6
APUD tumours	8	75	75
Small bowel (adeno)	6	83·3	83·3
Colon (adeno)	283	78·8	86·2
Anus (squamous)	3	66·7	100
Total			
Adenocarcinoma	458	76	85·6
Squamous cancer	60	60	63·3

Fig. 3 illustrates results in 4 representative patients with colorectal cancer.

Case 1: D. B., a 78-year-old female, presented in April 1978 with a 3-year history of change of bowel habit. A CEA level was >1200 μg/l and barium enema revealed a caecal cancer. She underwent a right radical hemicolectomy for a well-differentiated C2 cancer, and 1 month later her CEA had fallen

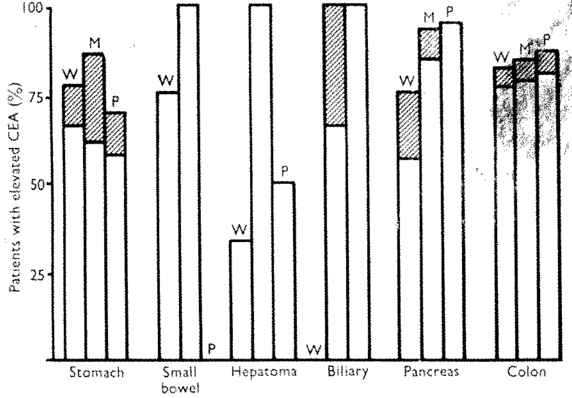

Fig. 1. Patients with gastrointestinal neoplasms divided by cellular differentiation (W, well, M, moderately and P, poorly differentiated) showing the percentage with an elevated CEA at the time of tissue diagnosis (white bars) and the total percentage that develop an elevation at any time (hatched bars).

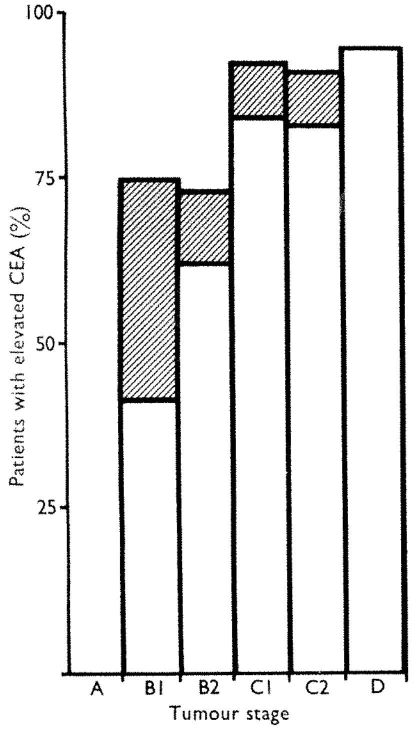

Fig. 2. Patients with colorectal cancer divided by stage showing the percentage with an elevated CEA at the time of tissue diagnosis (white bars) and the total percentage that develop an elevation at any time (hatched bars).

to 4 µg/l. The CEA then rose to 6 µg/l at 3 months, and 185 µg/l at 9 months; liver scan and chest X-ray at that time revealed multiple metastases.

Case 2: H. D., a 70-year-old female, presented in December 1975 with a change of bowel habit. Investigation revealed a colonic mass and a CEA of 9·6 µg/l. A colectomy was performed for a moderately differentiated C2 cancer of the descending colon. In June 1976 a repeat CEA was still elevated at 7·6 µg/l and further investigation revealed a small rectal tumour (<1 cm in diameter). Following an abdomino-perineal resection CEA levels fell to normal and the patient remains symptom-free with normal CEA levels 18 months later.

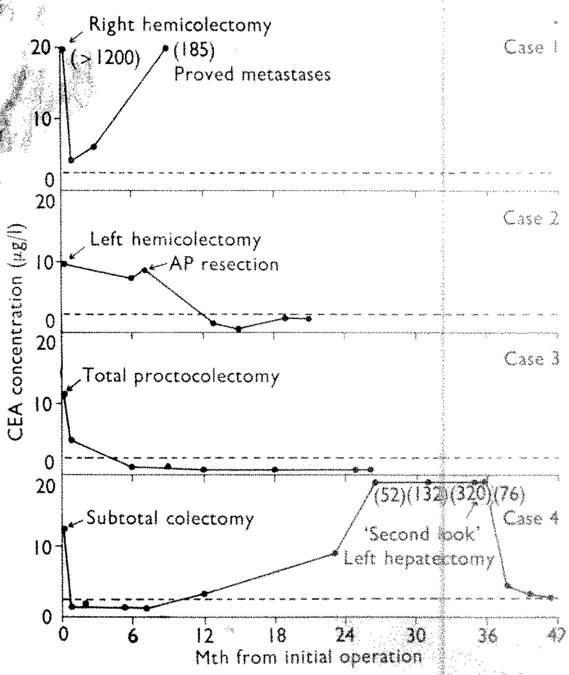

Fig. 3. Results of serial CEA estimations performed on 4 patients with colorectal cancer.

Case 3: M. H., a 41-year-old female with known ulcerative colitis, was seen in January 1975 when a routine check-up disclosed two colonic strictures. Her CEA at this time was 11·2 µg/l. A total proctocolectomy was performed for a moderately differentiated B2 cancer of the splenic flexure, and her CEA levels fell to normal. She is clinically free of tumour with normal CEA levels 2 years later.

Case 4: H. B., a 69-year-old male, presented in November 1973 with a change in bowel habit. Investigation revealed two colonic cancers and a CEA of 12·4 µg/l. Subtotal colectomy was performed for two moderately differentiated C2 cancers and the CEA fell to 1·2 µg/l. Serial CEA levels began to rise 12 months postoperatively and reached 52 µg/l at 28 months; investigations at this time showed no evidence for recurrent or metastatic disease. The CEA remained elevated and, on this evidence alone, a 'second look' laparotomy was performed at 36 months. A solitary metastasis in the left lobe of the liver was removed; CEA concentration was 2·8 µg/l 6 months later.

Discussion

Several antigens have now been described that are present in significant amounts only in neoplastic and fetal tissues (Gold and Freedman, 1965; Abelev, 1974; Gelder et al., 1978). The development of radioimmunoassays allows reliable measurement of the plasma concentrations of these antigens, and several have now been evaluated as tumour markers. The description by Gold (Gold and Freedman, 1965) of CEA and initial reports of its specificity for entodermal cancers (Thompson et al., 1969; Nugent and Hansen, 1971) provoked widespread interest, and it is now the most thoroughly evaluated of the oncofetal antigens. Several assay techniques have been described for CEA: we have employed the Hansen Z-gel method (Hansen et al., 1971), which has been manufactured

Table III: NUMBER OF PATIENT[illegible] AN ELEVATED CEA

	No. of patients in group	No. of patients with a CEA greater than 2·5 µg/l	10·0 µg/l
Pancreatic cancer patients	52	[illegible]	20 (39%)
Other cancer patients	51	[illegible]	16 (31%)
Benign disease patients	[illegible]	31 (46%)	4 (6%)

Table IV: THE DIAGNOSTIC ABILITY OF AN ELEVATED CEA FOR MALIGNANT DISEASE TAKING TWO UPPER LIMITS OF NORMALITY

	CEA > 2·5 µg/l (%)	CEA > 10·0 µg/l (%)
Prevalence	60·6	60·6
Sensitivity	73·8	35·0
Specificity	53·7	94·0
Accuracy	65·9	58·0
Predictive value of a positive test	71·0 (3·1%)*	90·0 (10·6%)*
Predictive value of a negative test	57·1 (99·0%)*	48·5 (98·6%)*

The predictive value of a positive test is (true positive tests/all positive tests), and the predictive value of a negative test is (true negative tests/all negative tests).
* These predictive values may be recalculated and projected to a theoretical population with a 2 per cent prevalence of malignant disease, as shown in parentheses (Vecchio, 1966).

into kits by Hoffman–LaRoche. This assay is relatively simple, although it involves several steps and is time-consuming.

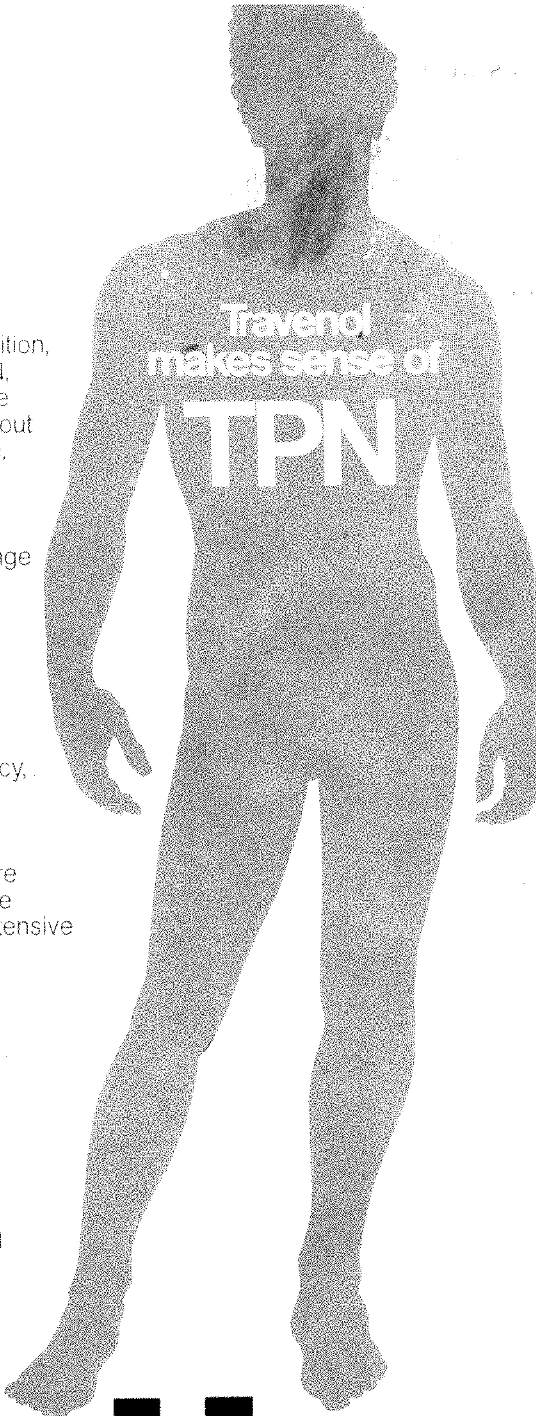
Experience with this assay in over 10 000 patients from Europe and America has shown that 97 per cent of normal people have a value less than 2·5 µg/l; the remaining 3 per cent tending to be heavy smokers (Roche Diagnostics, 1976). Initial evaluation of CEA in colonic cancer patients revealed an elevated level in 96 per cent (Thompson et al., 1969), but this was a selected group with advanced disease and a more realistic figure is around 80 per cent (Zamcheck, 1975; Martin et al., 1976). Further evaluation of CEA found values greater than 2·5 µg/l in patients with a variety of gastrointestinal tumours, particularly of the pancreas (Khoo and Mackay, 1973; Dilwari et al., 1975), where 90 per cent positive results have been frequently reported, and also in other malignant disorders, though the percentage of positive results is not as high (Stewart et al., 1974; DiSaia et al., 1977). Our figures (*Tables I, II*) are in agreement with published series.

CEA assay cannot provide a reliable screening test for malignant neoplasms as levels are frequently elevated in patients with benign disease. Elevated levels have been found in association with pancreatitis (Dilwari et al., 1975), cholecystitis (Martin et al., 1976), inflammatory bowel disease (Martin et al., 1976), liver disease (Bullen et al., 1977) and rectal polyps (Doos et al., 1975; Martin et al., 1977). While this reduces the value of CEA assay as a screening test for malignant disease, an elevation can be used to monitor these diseases. Bullen et al. (1977) found an elevated CEA in up to 70 per cent of patients with liver disease and found the CEA level to be useful in distinguishing acute from chronic liver damage. Martin et al. (1977) reported an elevated CEA in 40 per cent of patients with rectal polyps and noted that he level fell to normal after polypectomy. It has been suggested that the value of CEA as a screening test for malignant disease could be improved by taking a level of 10 µg/l as the upper limit of normal (Concannon et al., 1973, 1974). CEA levels were assayed as part of a prospective diagnostic protocol for pancreatic cancer at this institution and the results have been reported elsewhere (Wood and Moossa, 1977). To illustrate the effect of increasing the upper limit of normal from 2·5 to 10 µg/l we have evaluated the test in a group of 170 patients (*Tables III, IV*).

From *Table III* it can be seen that while 83 per cent of pancreatic cancer patients had a CEA of over 2·5 µg/l, so did 46 per cent of patients with benign disease. The effect of increasing the upper limit of normal to 10 µg/l is to reduce the positive results in benign disease to 6 per cent, at the expense of a large drop in the positive results for pancreatic cancer (39 per cent). The predictive value of a positive test must remain significantly greater than the prevalence of the disease sought (Vecchio, 1966); an effective screening test requires a high predictive value for a positive test to minimize the number of patients without malignant disease being subjected to further, and sometimes extensive, investigation. These values are shown in *Table IV* for a highly selected group of patients. When they are projected to a theoretical population with a 2 per cent prevalence of malignant disease (figures in parentheses in *Table IV*), a better estimation of the value of CEA as a screening test can be obtained. It is evident that the preferred normal level is 10 µg/l as a minimal loss in the predictive value of a negative test results in a threefold increase in the predictive value of a positive test. Even at this level, however, only 1 in 10 of the patients with a positive CEA will have malignant disease. CEA assay is thus a poor screening test for malignant disease.

A good correlation has been found between positive CEA tests and tumour staging (Zamcheck et al., 1972; Martin et al., 1976). Furthermore, the larger the tumour mass, the more CEA is produced, the highest levels being found in patients with metastatic disease, as shown in *Fig.* 2. Some authors (Martin et al., 1976) have shown that more CEA is produced by the better differentiated tumours, but we are unable to confirm this finding (*Fig.* 1); our results show no correlation between cellular differentiation and CEA levels. The effect of differentiation is difficult to estimate on its own, as the well-differentiated tumours are sometimes small and therefore less likely to produce large amounts of CEA. *Tables I* and *II* show that a small percentage of patients with an initially normal CEA develop elevations during the course of their disease. The clinical significance of this observation has not been fully evaluated and requires further investigation.

Attention has turned to the ability of serial CEA assay to detect recurrent or residual tumour at an early stage (Dhar et al., 1972; Sugarbaker et al., 1976; Martin et al., 1977). The success of Ellis and others with 'second look' procedures has prompted a more aggressive approach to the management of recurrent cancer; the success of these operations relies on early detection of recurrent tumour. An elevated CEA should fall to normal within 1 month of curative resection of a cancer (Zamcheck, 1975; Martin et al., 1976): this is well shown in *Case* 3, where the level fell below 2·5 µg/l after surgery and has remained low as the patient has remained clinically free of tumour. Failure of an elevated CEA to fall after resection is



For total parenteral nutrition, Travenol makes SYNTHAMIN, amino acid injections, in three concentrations with and without a balanced electrolyte profile. A further concentration is available with an energy substrate.

To complement this range of solutions, Travenol provides specialized "V" and "W" administration sets, and both central and peripheral venous catheters.

Travenol also supplies the means for compounding TPN regimens in the pharmacy, using VIAFLEX plastic containers for non-air-dependent administration.

All Travenol products are supported by comprehensive technical back-up and an extensive in-service organization.

Synthamin amino acid injections

Presentation
Synthamin injections [illegible] non-pyrogenic solutions [illegible] and non-essential L-[illegible] provided with or with[illegible] Synthamin [illegible] is also provided [illegible] carbohydrate as Sorbitol.

Indications
Parenteral nutrition.

Dosage and Administration
Dosage depends on patient's metabolic requirement and clinical response. For intravenous administration an associated source of non-protein energy should be administered of not less than 0.75MJ (180Kcal) per gram of nitrogen administered.

Contraindications
Severe liver disease. Solutions with electrolytes are contraindicated in renal failure.

Precautions
As with all hypertonic solutions, vein irritation may occur.

Availability
Synthamin 7S (PL0116/0043)
500ml £4.20 1000ml £7.56
Synthamin 9 (PL0116/0054)
500ml £5.15
Synthamin 9 (PL0116/0067)
500ml £4.80 without electrolytes.
Synthamin 14 (PL0116/0055)
500ml £7.35
Synthamin 14 (PL0116/0068)
500ml £7.00 without electrolytes.
Synthamin 17 (PL0116/0056)
500ml £8.90
Synthamin 17 (PL0116/0069)
500ml £8.55 without electrolytes.

Full prescribing information is available from Marketing Services Department.

Snowden Pencer

DIAMOND JAW® DIAMOND EDGES® DISTRIBUTED ONLY BY DOWNS

DIAMOND-EDGES Scissors
High quality stainless steel blades are permanently bonded with a hard tungsten carbide insert, diamond ground and honed for exceptional keenness, so they practically never need sharpening.

DIAMOND-JAW Forceps
The multi-purpose Diamond-Jaw Atraumatic Tissue Forceps, with their tough, solid tungsten carbide inserts, serve the grasping functions of both the conventional rat-tooth tissue forceps and also serrated forceps for delicate tissue.

DIAMOND-JAW Needle Holders
Hard, sharp teeth cut in solid tungsten carbide inserts hold suture needles really securely preventing rotation or slipping in use.

Downs Surgical

Remember that Snowden-Pencer the originators of tungsten carbide inserts, with their distinctive gold handles, are distributed **only** by Downs, so send the coupon now for details.

To: Downs Surgical Ltd., Church Path, Mitcham, Surrey. CR4 3UE Please send me full details of the Snowden-Pencer instrument range.

SHOCK

aprotinin

Trasylol®

increases the chances of survival in traumatic-haemorrhagic shock

The results of a large German field study[1]: Marked reduction of mortality when Trasylol was applied early. Precise clinical investigations in 70 shock patients by an Australian double-blind study[2] provided an explanation and further proof for the effectiveness of Trasylol in shock: With Trasylol development of post-traumatic respiratory insufficiency (shocklung) was less frequent.

Bayer

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short-term infusion (5 ml/min to the patient in the recumbent position); thereafter every 4 hours 200,000 KIU slowly i.v.

Important
Trasylol may in very rare cases (less than 0.1%) cause hypersensitivity reactions.

Presentation

indicative of incomplete excision or recurrence; this is seen in *Case* 2, where a persistently elevated CEA was found in the presence of a second or recurrent colonic cancer. Removal of the residual cancer resulted in the CEA level returning to normal. In *Case* 1 we see the effect of removing a bulky tumour, with CEA falling to near normal levels, only to rise as the disease progresses. Several authors (Dhar et al., 1972; Zamcheck, 1975; Martin et al., 1976) have reported CEA elevation in patients with recurrent cancer before any other clinical investigation revealed tumour, and the development of a rising CEA after apparent curative surgery now provides good grounds for a 'second look' operation, even when all other investigations are normal. This is illustrated well by *Case* 4, where the CEA level increased and remained elevated as the result of a solitary hepatic metastasis which was undetected by other investigations for over 1 year. The correlation of CEA and the response to chemotherapy has also been investigated (Skarin et al., 1974); changes in CEA levels correspond well to progression or regression of the disease. The serial assay of CEA also appears to be useful in the management of some non-gastrointestinal tract tumours, including breast and gynaecological tumours (Stewart et al., 1974; DiSaia et al., 1977).

CEA has been thoroughly evaluated over the past 10 years and its place in clinical practice can now be defined. Measurement of this antigen has little to offer in the detection of malignant disease, but a pre-treatment estimation with serial follow-up provides good estimation of the completeness of excision or effectiveness of therapy. A persistently high or rising level indicates progression of the cancer. A rising post-operative CEA level is a good indication for a 'second look' procedure.

Arterial obstruction of the upper limb in Buerger's disease: its incidence and primary lesion

MASAFUMI HIRAI AND SHIGEHIKO SHIONOYA*

SUMMARY

In the present study, the incidence of upper extremity involvement and the primary lesion of the arm in Buerger's disease were investigated with special regard to arteriographic findings in the upper limb. Of 34 patients with Buerger's disease admitted to our hospital during the 12-month period from March 1977 to February 1978, in 31 cases (91 per cent) the existence of arterial obstruction of the upper limb was confirmed. From the results of arteriographic study in 78 arms, the primary lesion of Buerger's disease appears to develop most frequently in the digital arteries. However, it is possible for the disease to develop independently in the arteries of the hand, or in the radial or ulnar artery. Although the aetiology of Buerger's disease is not definitely known, it is suggested that repeated blunt injury to the hand or fingers is involved in the evolution of the disease as well as in the appearance of symptoms.

In Buerger's disease, arterial obstruction may occur not only in the leg but also in the arm, and the presence of upper extremity involvement has been used as one of the criteria for differentiation of this disease from arteriosclerosis obliterans (Barker, 1962; McKusick et al., 1962; McPherson et al., 1963; Szilagyi et al., 1964; Goodman et al., 1965; Thieme et al., 1965; Mozes et al., 1970; Morris-Jones and Jones, 1973). The incidence of blood flow disturbance of the upper limb in Buerger's disease has been reported to be from 14 to 100 per cent (*Table I*). It is considered that this great variance in the reported incidence can be attributed to the different criteria used for the diagnosis of Buerger's disease and also to the different methods used for confirmation of an occlusive lesion. Various methods have been used for diagnosis of arterial obstruction (Coffman and Cohen, 1971; Henderson and Hackett, 1978; Hirai, 1978), but no method is superior to arteriography as a diagnostic aid for accurate confirmation of the obstruction.

In the present study, in order to determine the precise incidence of arterial obstruction of the upper limb in Buerger's disease, arteriography was employed in both symptomatic and asymptomatic limbs in cases diagnosed clinically as having Buerger's disease. Furthermore, development of the primary lesion of Buerger's disease and its evolution were investigated on the basis of arteriographic findings.

Figures in parentheses are percentages.

Patients and methods

During the 12-month period from March 1977 to February 1978, 34 patients with Buerger's disease were admitted to the Department of Surgery, Nagoya University Branch Hospital. In these patients, the presence of arterial obstruction of the upper limb was investigated by means of brachial arteriography, clinical findings and determination of digital blood pressure (Hirai, 1978). The diagnosis of Buerger's disease was based on the criteria described in previous papers (Shionoya et al., 1974; Hirai and Shionoya, 1978). In all patients studies were made of complete blood count, urinalysis, fasting blood sugar and serum cholesterol and chest X-rays and electrocardiograms were taken. In addition to clinical assessment femoral arteriography, which was carried out in 31 of 34 patients, was reviewed.

All patients were male and at the onset of their symptoms all were smokers. The initial symptoms of vascular disease appeared at a mean age of 36 years, with a range of 25–48 years. Only 2 patients were over 45 years at the first onset of symptoms. The mean duration from the onset of the disease to the time of this investigation was 6·5 years, with a range of 2 months to 23 years. All the patients were otherwise in good health and had no evidence of organic heart disease, arterial aneurysm, diabetes mellitus, radiographically demonstrable calcification of peripheral arteries or scleroderma. All the patients had normal blood cholesterol levels.

Superficial thrombophlebitis had occurred in 20 patients and 17 patients complained of intermittent claudication in the foot (Hirai and Shionoya, 1978). Involvement of the upper extremity was observed in 22 patients. It was confirmed by signs of digital ischaemia, such as cyanosis or gangrene, as well as by the absence of pulsation in the radial or ulnar artery in association with a positive Allen test (Allen, 1929). Thirty-one patients had at least one of these three manifestations. Twenty-seven patients had a history of or evidence of skin ulceration on the toes or fingers. Blood pressure measurement at the second toe (Hirai and Shionoya, 1978) revealed a significantly low blood pressure in at least one leg of all the patients, and arterial occlusion in the leg was confirmed by femoral arteriography in 31 patients. On arteriography the arteries proximal to the occlusion sites were seen to be regular and smooth. No intimal plaques or calcifications were visible.

Brachial arteriography was carried out in 30 of 34 patients. Retrograde puncture of the brachial artery was performed in the antecubital fossa and 15 ml of contrast medium (60 per cent of Conray) were injected rapidly by hand or automatic injector. Twenty films were exposed over a period of at least 15 s. The usual rate was 1 film per second.

To investigate the development of the primary lesion in Buerger's disease, arteriographic findings in a total of 78 limbs were studied, including 33 limbs in 24 patients undergoing brachial arteriography at our hospital before February 1977 and 45 limbs in 27 patients after March 1977.

Results

Incidence

In 31 of 34 patients (91 per cent) arterial obstruction in at least one upper limb was confirmed. In 27 of

these 31 cases arterial obstruction was detected by arteriography; in the remaining 4 cases it was confirmed by the presence of definitive signs of ischaemia, such as cyanosis or gangrene, as well as by the absence of wrist pulsations in association with a positive Allen test and a decreased digital pressure. In 3 other cases arteriography, which was performed in both arms, failed to reveal arterial obstruction.

Of 27 cases shown by arteriography to have arterial obstruction, 26 underwent bilateral arteriography. In 8 of these 26 cases obstruction was found on one side only, with no obvious arterial obstruction on the opposite side. An inspection of the site of obstruction in these 8 cases revealed that 5 cases had obstruction of the digital artery, 2 of the ulnar artery and 1 of the radial artery.

Arteriographic findings

Seventy-eight limbs were submitted to brachial arteriography (*Table II*). Thirty-three of these investigations were carried out before February 1977, being performed mainly in patients with severe digital ischaemia. During this period, obstruction of both the radial and ulnar artery was overwhelmingly prevalent. The remaining arteriograms (45), performed from March 1977 onwards, were carried out irrespective of whether or not there were symptoms or signs in the arm. In this group, obstruction of the more distal arteries was detected with increased frequency. In 39 hands without clinical evidence of ischaemic disease the most common site of occlusion was the digital artery (*Figs*. 1, 2).

Table II: THE SITE OF ARTERIAL OCCLUSION IN 78 ARMS

	April 1967–February 1977 ($n = 33$)		
Involved artery	Ischaemic symptoms	No symptoms	Total
Radial and ulnar	15	2	17 (52)
Radial only	0	0	0
Ulnar only	4	2	6 (18)
Hand*	5	2	7 (21)
Digital	2	1	3 (9)
	March 1977–February 1978 ($n = 45$)		
Involved artery	Ischaemic symptoms	No symptoms	Total
Radial and ulnar	5	0	5 (11)
Radial only	1	0	1 (2)
Ulnar only	7	13	20 (44)
Hand*	0	3	3 (7)
Digital	0	16	16 (36)

* Hand arteries included deep or superficial palmar arch, common digital artery, metacarpal artery and princeps pollicis artery.

Figures in parentheses are percentages.

By further studying the arteriographic findings in individual cases with involvement of the digital artery, it was found that in some cases the whole length of the

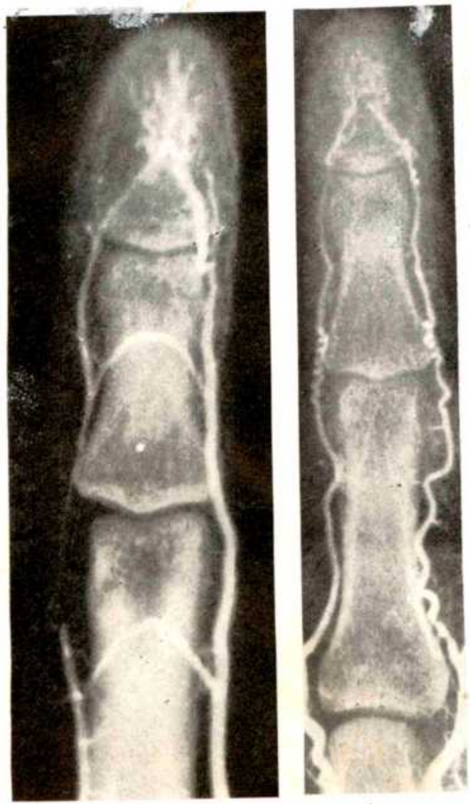

Fig. 3. Segmental occlusion (*a*) and tortuosity (*b*) of the digital artery adjacent to the interphalangeal joint.

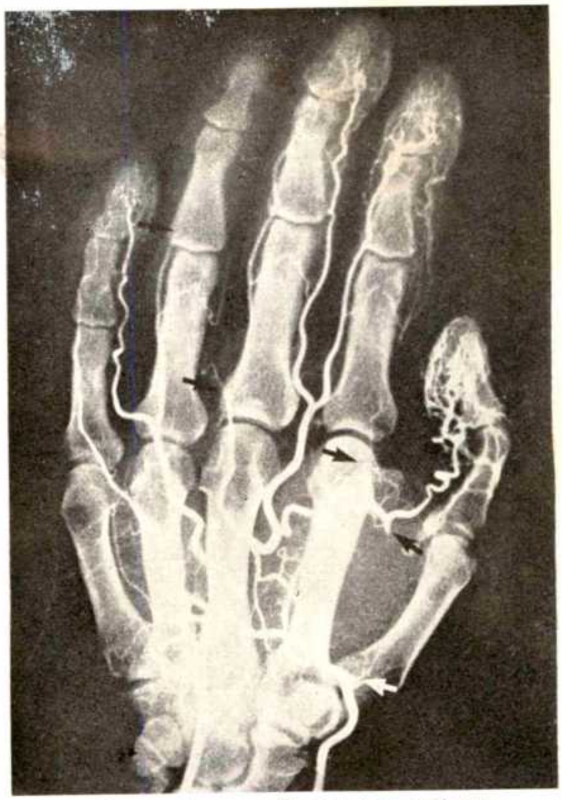

Fig. 4. A 42-year-old patient. The arteriogram shows segmental occlusion of the princeps pollicis artery, complete occlusion of the lateral digital artery of the index finger and occlusion of the lateral digital artery at its origin and the medial digital artery at the proximal interphalangeal joint of the ring finger.

artery was involved and only the distal part in others. In addition, segmental occlusive lesions of the digital artery were observed (*Figs*. 1–3). The segmental type of obstruction accounted for 36 per cent of cases in which occlusive lesions were detected only in the digital artery. Frequently, this type of occlusion was observed adjacent to the interphalangeal joint. In addition to obstructive lesions, the digital artery sometimes exhibited tortuosity. This was observed in 56 per cent of cases. There were relatively large tortuosities and also fine ones. It was noted that fine tortuosity was often seen adjacent to the interphalangeal joints, as were the segmental occlusive lesions (*Fig*. 3).

With regard to the arteries of the hand, such as the deep or superficial palmar arches, common digital artery, metacarpal artery or princeps pollicis artery, diffuse occlusion associated with an involved radial or ulnar artery was a common finding. However, segmental occlusive lesions were also observed in this area (*Figs*. 4, 5). Lesions of the radial and ulnar arteries included obstruction involving the whole length of the artery, segmental obstruction and irregularities that were often seen adjacent to the wrist joint (*Figs*. 5, 6). Other than these, in 4 cases findings similar to those of hypothenar hammer syndrome (Conn et al., 1970; Benedict et al., 1974) were encountered, i.e. localized lesions of the ulnar artery were detected near the hook of the hamate bone (*Fig*. 7). In these patients no history of blunt trauma to the palm which might have caused hypothenar hammer syndrome was obtained. In all but one of 59 cases that were found to have obstructions in the arteries of the hand, or in the radial or ulnar artery, occlusive lesions of the digital artery were also observed. In an exceptional case, which showed obstruction involving the whole length of the ulnar artery, no clear evidence of obstruction was seen in the other arteries, including the digital artery.

Discussion

The incidence of upper extremity involvement in Buerger's disease has been reported as from 14 to 100 per cent (*Table I*). This great variance among investigators might be explained mainly by the different criteria used for the diagnosis of Buerger's disease and the different methods used for confirmation of an occlusive lesion. McPherson et al. (1963), who reported an incidence of 100 per cent, considered that the presence of an occlusive lesion in the upper limb was an essential requirement for a diagnosis of Buerger's disease. Mozes et al. (1970), who reported the next highest incidence (77 per cent), diagnosed Buerger's disease clinically if any two of three manifestations, i.e. upper extremity involvement, superficial thrombophlebitis or Raynaud's phenomenon, were seen. Naturally, the incidence becomes high if such diagnostic criteria are employed. In the present study

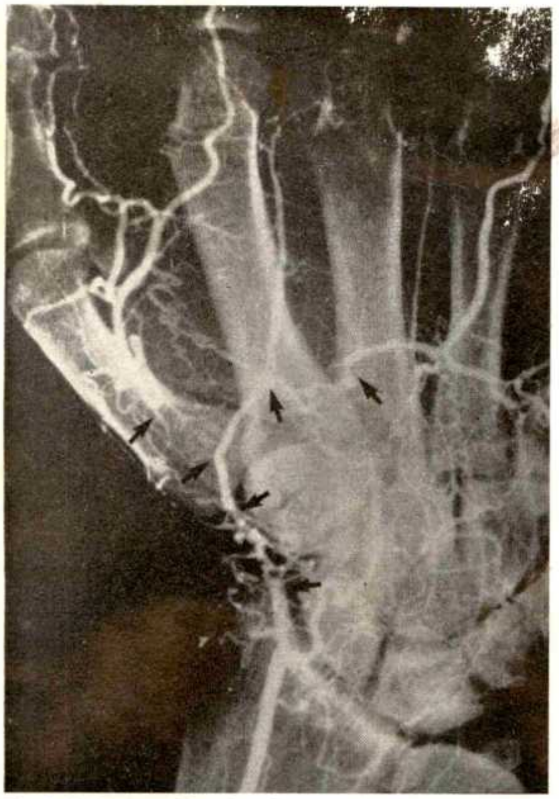

Fig. 5. A 51-year-old patient. Segmental occlusions are seen in the radial artery, deep palmar arch and princeps pollicis artery. The ulnar artery is completely occluded.

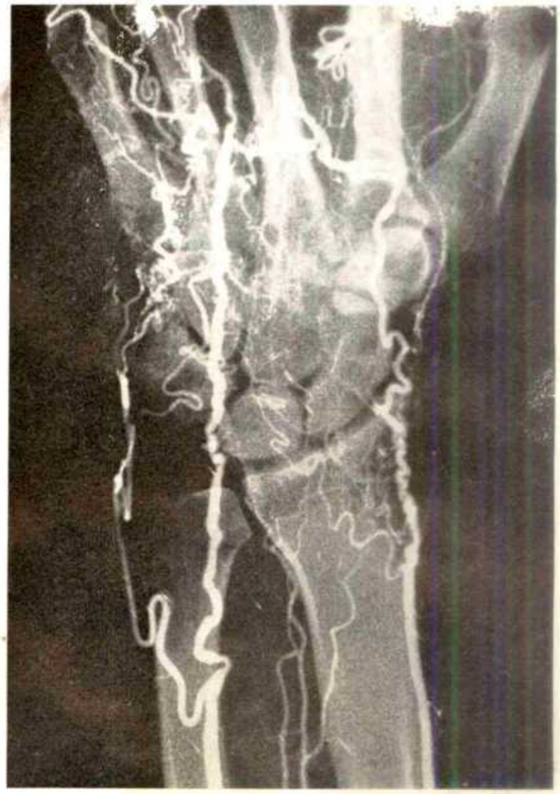

Fig. 6. A 46-year-old patient. Severe irregularities are observed in the radial and ulnar arteries adjacent to the wrist.

Buerger's disease was diagnosed on the basis not only of the presence of upper extremity involvement, but also on smoking habit, male sex, comparative youth and coexistence of thrombophlebitis or foot claudication, in the absence of findings suggesting other diseases. Furthermore, arteriographic findings were also considered. These criteria for the diagnosis of Buerger's disease have been widely used by other authors (Barker, 1962; McKusick et al., 1962; Szilagyi et al., 1964; Goodman et al., 1965; Thieme et al., 1965; Schatz et al., 1966; Eastcott, 1969; Inada and Katsumura, 1972; Kummer et al., 1977).

Goodman et al. (1965) reported a 74 per cent incidence of upper extremity involvement in Buerger's disease and commented that their high incidence was not exceptional, it was merely a reflection of their prime concern to determine the frequency of the disease. In our present study, only 6 of 34 patients were admitted to hospital complaining of symptoms of blood flow disturbance in the upper limb either associated with lower limb symptoms or alone. None the less, careful clinical questioning and physical examination revealed that 22 cases had arterial occlusion in the upper limb. Therefore, if the fact that arterial occlusion may occur in the arm as well as in the leg is always taken into account whenever physicians see patients, arterial obstruction of the upper limb can be detected with increased frequency. In our present study, however, in which, since March 1977, arteriography was carried out regardless of the absence of clinical evidence of the disease, arterial

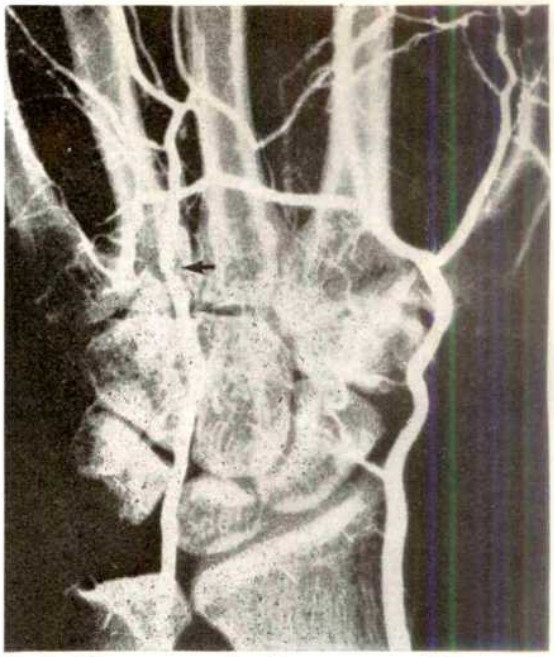

Fig. 7. A 36-year-old patient. Severe stenosis of the ulnar artery is observed near the hook of the hamate bone. This patient had no history of blunt trauma to the palm.

obstruction of the upper limb was found to be present in 91 per cent of the cases. These findings indicate that an arterial occlusive lesion does not always produce ischaemic signs in the limbs (Holstein and Sager, 1973; Hirai and Shionoya, 1976). However, the fact that arterial lesions of the upper limb can be seen in an extremely high percentage of patients is of great importance in advising the patients, as described below.

Regarding the results of arteriographic studies before February 1977, when arteriography was performed mainly in patients with severe digital ischaemia, occlusion of both the radial and ulnar arteries was the most frequent finding. From the analysis of arteriographic findings in advanced cases, it appears that the primary lesion of the upper limb in Buerger's disease frequently occurs in the radial or ulnar artery. However, obstruction of the more distal arteries was detected with increased frequency after March 1977. In cases without clinical evidence of ischaemic disease, the most common site of occlusion was the digital artery. Moreover, in cases with arterial occlusion in the arteries of the hand, the radial or the ulnar artery, an association with obstruction of the digital artery was observed in all but one case. From these findings, it might be considered that the primary lesion of Buerger's disease develops most frequently in the digital artery (Kamiya, 1964; Goodman et al., 1965).

The pattern of obstruction of the digital artery was studied and segmental obstruction was seen in 36 per cent of cases, indicating that the primary lesion in the digital artery does not always develop at the tip of the fingers. In addition, the fact that segmental occlusions are observed in the arteries of the hand and in the radial and ulnar arteries suggests that Buerger's disease can develop not only in the fingers but also in these parts independently.

The real aetiology of Buerger's disease is still unknown. It is assumed, however, that repeated blunt injury to the hand or fingers may be involved in the development of the disease, as well as in the appearance and exacerbation of its symptoms (McKusick et al., 1962). Development of obstruction, irregularity and tortuosity in the area adjacent to the joint all suggest that repeated joint movement constitutes one of the factors responsible for evolution of the disease. Furthermore, it was recognized by taking a detailed history that in two patients in our series digital ischaemic signs developed after using their hands for several months at their jobs. In ulnar arterial disease resembling hypothenar hammer syndrome, it appears that mild blunt trauma to the palm, which exerts no influence in normal subjects, may play a role in the development of this lesion in the presence of underlying Buerger's disease.

The above-described arteriographic findings are not considered to be necessarily specific for Buerger's disease, since we observed segmental obstruction, tortuosity of the digital arteries and disease of the ulnar artery near the hook of the hamate bone in arteriosclerosis obliterans and Raynaud's phenomenon. None the less, since arterial obstruction of the upper limb occurs in a high percentage of patients with Buerger's disease, it is recommended that injuries to the hand or fingers through occupation, sport, hobby or habits should be avoided as much as possible in all [illegible] Buerger's disease, in addition to cessa[illegible] (Goodman et al., 1965; Schatz et al., [illegible], 1970; Kummer et al., 1977) and [illegible] exposure of the hand to cold (McKusick et al., 1962; Hill et al., 1973).

Late revascularization of the lower limb following acute arterial occlusion

J. V. ROBBS AND L. W. BAKER*

SUMMARY

Thirty-four patients presenting with signs of grave ischaemia of the lower limb following acute arterial occlusion had revascularization procedures performed. Fifteen of the incidents followed embolism or thrombosis and 19 were due to a traumatic cause.

Limb salvage was achieved in 67 per cent of the non-traumatic group and in 56 per cent of the traumatic group. Severe complications such as crush syndrome and disseminated intravascular coagulation occurred but there were no deaths.

No significant adverse factors with regard to limb prognosis could be defined.

We feel that late revascularization in the absence of major gangrene is worth while provided that facilities for critical postoperative care exist.

IRREVERSIBLE limb ischaemia following acute arterial occlusion is difficult to define. Whether to revascularize or not may severely tax clinical judgement, because the consequences of re-establishing circulation in a dead limb may be life-threatening. By the same token, major amputation of a viable limb is undesirable. We report our experience of revascularization of the lower limb in the presence of grave ischaemia. All results have been assessed over a period of 3 months to 3 years.

Patients

During a 3-year period, 34 patients presented after major acute arterial occlusion with clinical signs often regarded as indicating irreversible ischaemia. These signs, present in all patients, were an 'ice-cold' limb with skin mottling, anaesthesia and total muscle paralysis. In addition, 16 patients (47 per cent) presented with significant muscle rigidity involving one or more fascial compartments.

The patients' ages ranged from 8 to 75 years (mean 31 years) and 25 were males. Non-traumatic acute arterial occlusion occurred in 15 patients, due to embolism (8) or thrombosis (7). The source of the embolus was the left atrium in 2 patients with atrial fibrillation, a cardiac mural thrombus in 5 patients with ischaemic heart disease and a grossly dilated ventricle in 1 patient with cardiomyopathy. The delay before presentation to hospital ranged from 4 h to 10 days (mean 8 days).

The sites of arterial obstruction were the femoropopliteal segment (8), the aortic bifurcation (4), the iliac artery (1), the popliteal artery (1) and distal vessels (1).

Associated diseases in 10 patients included hypertension (2), congestive heart failure (4), cerebrovascular disease (2) and diabetes (2).

Nineteen patients with acute arterial occlusion complicating penetrating (4) or blunt (15) trauma presented 4–72 h after injury (mean 24 h). There was partial vessel wall disruption in 4 patients, total disruption in 6 and thrombosis in 9.

The vessels involved were the popliteal (10), superficial femoral (8) and the iliac (1) arteries.

Associated injuries included long bone fractures or dislocations in 14 patients, severe head injury in 3 patients and a penetrating abdominal wound in 1 patient.

Management and results (*Table I*)

Non-traumatic group

Balloon catheter embolectomy via the femoral route was performed in all cases.

Regional heparin was routinely infused in a concentration of 10 000 units of heparin per litre of isotonic saline. Systemic heparin was administered for at least 7 days after the operation. In addition, when the cardiac status permitted LMW dextran (Rheomacrodex) was infused at the rate of 500 ml per 12 h, for 36 h.

Thirteen patients had open two-compartment fasciotomy from knee to ankle on the medial side and along the full length of the extensor compartment.

Limb salvage was achieved in 10 patients (67 per cent), of whom 9 are ambulant. Return of pedal pulses was noted in 7 patients. One patient developed intermittent claudication 6 months after operation.

Amputation within 48 h was necessary in 5 patients (33 per cent), below-knee in 2 and mid-thigh in 3. In at least 1 patient revascularization permitted a more distal amputation. Two patients developed foot drop due to extensor compartment infarction.

One patient with atrial fibrillation developed paraplegia, with a sensory level at L1, despite restoration of all peripheral pulses. No sign of recovery is evident 6 months after operation. Postoperatively this patient developed iliac vein thrombosis despite heparin administration and survived two episodes of major pulmonary embolism. Inferior vena caval interruption was eventually performed.

Traumatic group

Nineteen patients with arterial injuries were treated by vein grafts (15), end-to-end arterial repair (2), lateral suture (1) and thrombectomy with vein patch angioplasty (1). Regional heparinization and balloon catheter thrombectomy were routinely employed.

All patients received an intravenous fluid load and 10 g of mannitol intraoperatively. Broad spectrum antibiotics were administered in all cases. Open fasciotomy was performed in 17 cases.

Orthopaedic injuries were treated on their merits in 14 patients, mainly by external fixation. Craniotomy was necessary in 2 patients and laparotomy in 1 patient.

One patient died due to a head injury within 24 h of operation and has been excluded from further analysis.

Limb salvage was achieved in 10 patients (56 per cent). Nine patients are ambulant. Severe causalgia precludes ambulation in 1 patient. Peripheral pulses have been restored in 7 patients.

Major amputation became necessary in 8 patients (44 per cent), below-knee in 3 and mid-thigh in 5. Five amputations were necessary within 48 h of operation owing to failure of the arterial repair. Three patients required amputation within 7 days. The indications were sepsis, with massive secondary haemorrhage from the arterial repair, necessitating a major vessel ligation in 2 patients and severe rest pain

Table III: COMPARISON OF CLINICAL FEATURES IN LIMB SALVAGE GROUP AND MAJOR AMPUTEES

			Site of obstruction					Clinical signs				
	Mean age (yr)	Mean time interval (d)	A	I	F	P	D	'Ice-cold' with mottling	Anaesthesia	Paralysis	Significant muscle rigor	Associated fracture
Limb salvage ($n = 20$)	30·8	3·0	4 (20)	0	11 (55)	5 (25)†	0	20 (100)	20 (100)	20 (100)	7 (35)†	7 (35)†
Major amputation ($n = 13$)	29·6	3·3	0	2 (15·4)	4 (30·8)	6 (46·2)†	1 (7·7)	13 (100)	13 (100)	13 (100)	9 (69·2) †	6 (46·2)†

* n is the total number of patients, which excludes 1 death occurring during the first 24 h (cerebral injury).
Figures in parentheses are percentages.
A, Aorta; I, iliac; F, femoral; P, popliteal, D, distal.
† Difference not significant ($P > 0·05$).

in 1 patient. Transmetatarsal amputation was necessary in 2 patients for minor gangrene.

Nine patients developed additional complications (*Table II*). The crush syndrome was successfully treated by haemodialysis in 2 patients, one of whom developed disseminated intravascular coagulation.

One patient suffers causalgia 2 years after operation despite sympathectomy. Foot drop in 3 patients has been satisfactorily managed by splintage. Tibial oesteitis in 1 patient responded well to repeated local surgery. One patient has troublesome oedema.

Comparison of clinical features among limb salvage group and major amputees (Table III)

Statistical comparisons were made using χ^2 analysis ($2 \times K$ contingency table).

The two groups did not differ significantly in mean age or in respect of the average time interval between the insult and surgical treatment. However, popliteal artery occlusion was more common in major amputees (46 per cent) than in the limb salvage group (25 per cent) ($P > 0·05$), and the only patient in the series with more distal occlusion was eventually submitted to amputation.

All patients in both groups presented with an 'ice-cold' limb with skin mottling, anaesthesia and total paralysis. Rigor involving one or more muscle groups was found in 7 (35 per cent) of the limb salvage group and in 9 (69 per cent) of the major amputees. This difference just fails to attain statistical significance ($P > 0·05$).

Associated long bone fractures were present in 7 (35 per cent) of those whose limbs were salvaged and in 6 (46 per cent) of those with major amputations ($P > 0·05$).

Discussion

Although it has been shown that the limb salvage rate is decreased by an increasing time interval between the insult and surgical treatment (Martin et al., 1969; Edwards, 1973; MacGowan and Moneeram, 1973; Thompson et al., 1976), there is general agreement that revascularization should be attempted provided that the limb is viable. Assessment of viability, however, can be extremely difficult (Thompson et al., 1976). Revascularization is contraindicated with advanced muscle rigidity, but mild rigidity should not preclude the procedure (Thompson et al., 1976). Edwards (1973) suggests that revascularization may be attempted in the presence of patchy skin necrosis. Similarly, Martin et al. (1969) indicate that there is little to lose by attempting revascularization in the [redacted] frank cation (E , 1973; Thom

All lim oubtful viability. The ollowing trauma, mainly because of iated soft tissue damage with destruction aterals and increased susceptibility to infection (Robbs and Baker, 1978a, b).

At operation back-bleeding is an unreliable index of distal arterial patency as short collaterals may cause this in the presence of distal discontinuous clot (Fogarty, 1970; Provan and Ransford, 1970; Thompson et al., 1976). The only reliable method of assessment is intraoperative angiography (Fogarty, 1970; MacGowan and Moneeram, 1973; Thompson, 1974) and we have adopted this practice as a routine. The popliteal vessels may then be explored if indicated (Fogarty, 1970; Kartchner, 1972).

The administration of systemic intravenous heparin for a 7-day period has been our routine practice (Fogarty, 1970; Kartchner, 1972; MacGowan and Moneeram, 1973; Thompson et al., 1976). Long term anticoagulant therapy is reserved for patients with peripheral embolization of cardiac origin (Kartchner, 1972).

Broad spectrum antibiotic therapy is indicated for extensive soft tissue injury and in patients with open fasciotomy. We perform fasciotomy in limbs that exhibit marked tissue turgor increase initially, or if this becomes evident 24–48 h later. We prefer open two-compartment fasciotomy extending from the knee to behind and below the malleolus medially and along the full length of the extensor compartment anteriorly. Sepsis has not been a major morbidity factor, and delayed primary suture or split skin grafting has been done once the wound is healthy. This is preferable to closed fasciotomy, where areas of deep fascia may be 'skipped' leaving 'tourniquet bands'.

Almost one-third of patients in the non-traumatic group developed complications. These proved life-threatening in only 1 patient, in whom iliac vein thrombosis with repeated major pulmonary embolism occurred despite adequate heparin administration. A careful haematological study of this patient failed to reveal a hypercoagulability state.

The incidence of complications was higher following trauma, and threatened life in 25 per cent of patients. In particular, myoglobinuria with acute renal shutdown may result from extensive soft tissue trauma aggravated by ischaemia and hypotension. This complication is anticipated in this group of patients and measures are instituted to [illegible] operative diuresis. In some series an attempt has been made to render the patients alkalotic (Thompson et al., 1976). Renal failure is recognized early and treated by dialysis.

Sepsis with breakdown of arterial repair has become less of a problem since a policy of antibiotic wound lavage and delayed primary closure has been adopted (Robbs and Baker, 1977, 1978a, b).

Although not statistically significant, the pattern of results indicates that more peripheral arterial occlusions and associated fractures worsen limb prognosis. Similarly, muscle rigor was more common in patients in whom late revascularization failed.

Conclusions

In the absence of frank major gangrene we believe that revascularization should be attempted in the doubtfully viable limb following acute arterial occlusion.

However, early detection and prompt and aggressive treatment of acute renal failure, DIC and septic complications are essential if disaster is to be prevented.

Although no deaths due to complications of the operation occurred in this series, these are life-threatening and surgery should not be attempted unless facilities for critical postoperative care are available.

Ascaris lumbricoides and perfo[illegible] a critical review

FRANK N. IHEKWABA*

SUMMARY

Ileal perforation due to typhoid bacilli is the commonest cause of peritonitis in the Tropics. Perforation due to Ascaris lumbricoides is rare. Three cases of ileal perforation believed to be due to A. lumbricoides are presented and the evidence critically reviewed. It is suggested that signs of heavy infestation with A. lumbricoides make a diagnosis of intestinal perforation more likely in a patient with an acute abdomen.

A COMMON cause of peritonitis in the Tropics is distal ileal perforation. In the majority of cases this perforation is due to the activity of typhoid bacilli in the Peyer's patches concentrated in this region of the small intestine. Tuberculous ulcers, strangulated obstruction, *Strongyloides stercoralis* and trauma are also recognized aetiological agents in perforation of the small intestine. The rare, solitary, small punched-out ulcer of the small intestine may also perforate (the so-called idiopathic perforation). Crohn's disease (regional ileitis) is rare in the Tropics, and although ulceration and perforation occur in this condition among Caucasians (Gow and Walsh, 1952; Waye and Lithgow, 1967), in Africans reports are unknown.

Intestinal perforation due to the ascarid has been suspected (Evans-Amfon, 1963), and, indeed, believed by some to be a real entity (Ovnatanian, 1959; Tkebuchava, 1960; Piggott et al., 1970; McNair, 1972), but proof has been difficult to come by owing to the frequent association of ascariasis with proved cases of typhoid fever.

This author has been concerned for some time with several cases of ileal perforation with peritonitis in which no evidence, clinical, microbiological, serological or histopathological, of typhoid infection could be found, but in which *Ascaris lumbricoides* were seen lying freely in the peritoneal cavity. The following cases are typical of the diagnostic dilemma.

Case reports

Case 1: A. K., male, aged 6 years, was admitted on 25 June 1977 to the Children's Emergency Department of University College Hospital, Ibadan, with a 3-day history of abdominal distension, nausea and loss of appetite. Vomiting had not been significant, but 6 days previously six round worms had been vomited. The bowels had not opened for 6 days. There was no fever.

On examination, the child did not look ill, though he was pale and mildly dehydrated. His temperature was 37 °C and his pulse 100/min, regular and of good volume. The respiration rate was 34/min. There were no palpable lymph glands. The abdomen, which was distended uniformly, was soft and not tender. There was no muscle guarding or rebound tenderness and a percussion note was resonant. Bowel sounds were present. The rectum was empty.

The haematocrit was 33 g/dl and the leucocyte count was $6{\cdot}2 \times 10^9$/l. Biochemical tests of plasma showed Na, 118 mmol/l; K, 3·2 mmol/l; Cl, 78 mmol/l; HCO_3, 28 mmol/l. The blood urea was 7·13 mmol/l.

Abdominal radiographs demonstrated a large number of round worms and a large subdiaphragmatic gas collection. A clinical diagnosis of typhoid perforation was made and plans for operation were instituted, with correction of fluid and electrolyte loss[illegible] laparotomy, thin, watery peritoneal fluid was found, with only minimal escape of small bowel contents. A segment of ileum, approximately 25 cm long, its distal end some 150 cm from the ileocaecal valve, was the seat of multiple perforations. The perforations were rounded and punched out with surrounding induration. Within the gut lay a bolus of *A. lumbricoides*, several plugging the small bowel perforations and preventing the escape of the gut contents. There was no mesenteric adenitis and the spleen was of normal size. No other pathology was evident.

The involved segment was resected with end-to-end anastomosis. After peritoneal toilet, the wound was closed in layers with a corrugated drain placed in the pelvis and brought out through a stab wound incision. The postoperative course was complicated by *Escherichia coli* septicaemia and wound infection by the same micro-organism.

Histopathological examination of the resected specimen did not reveal the typical typhoid picture. Blood, stool, urine and peritoneal exudate cultures were negative for salmonella. The Widal agglutination reaction was negative. The Heaf test was negative. The patient was discharged on the eighteenth postoperative day.

Case 2: A. S., male, aged 8 years, was admitted with a 5-day history of central abdominal pain associated with vomiting. The mother stated that the child had 'coughed' up a round worm the previous day. The abdominal pain had become worse in the 36 h before attendance at hospital. The child had lost his appetite, had become constipated and his abdomen was enlarged. The mother thought that the boy had had a fever the previous night, but there had been no headaches. He had been well and at school in the weeks before this illness.

Examination revealed a miserable-looking boy with only moderate abdominal pain. The pulse was 94/min and regular; his blood pressure was 110/60 mmHg and his temperature was 37·8 °C. The respiration rate was 26/min. No peripheral glands were palpable. The abdomen was full and firm, but guarding was only moderate. There was tenderness in all areas. Bowel sounds were absent. The rectum contained loose faecal matter and some mucus.

The haematocrit was 38 g/dl; the white cell count was $9{\cdot}3 \times 10^9$/l, with a normal differential count. Blood urea was 7·9 mmol/l; Na, 138 mmol/l; K, 3·8 mmol/l; Cl, 91 mmol/l; HCO_3, 20 mmol/l.

Radiographs of the abdomen showed some fluid levels as well as dilated loops of small intestine.

After appropriate preparation, laparotomy was performed. Thin, bile-stained peritoneal fluid was seen. The small bowel was distended proximal to a point about 30 cm from the ileocaecal valve. In this region, loops of bowel and omentum had attempted to surround some bile-stained intestinal contents walled over by a friable pyogenic membrane. When the loops were separated, two perforations, each about 6 mm in diameter, were seen, one near the antimesenteric border of the gut, the other about midway between the mesenteric and the antimesenteric borders. They lay 10 cm apart. Two ascaris worms were found lying in the right paracolic gutter. The liver and spleen were not enlarged.

The affected loop of bowel was brought out into the wound and isolated with moist abdominal packs. The perforations were rounded, indurated and punched out. The edges of the perforation were excised and submitted for histopathological examination. The defect was closed in two layers. The wound was closed in layers, with deep tension monofilament nylon sutures *in situ*. Apart from a mild wound infection, the patient

---

* Department of Surgery, University College Hospital, Ibadan, Nigeria.

made an uneventful recovery. The excised specimens were reported as showing non-specific inflammatory reaction.

Cultures of peritoneal fluid, stool, blood and urine were negative for salmonella. The Widal agglutination reaction failed to show a significant rise in titre after 10 days. The Heaf test was grade 1 positive.

Case 3: R. L., male, aged 8, was admitted with a one-day history of vague abdominal pain. He had vomited several times that day as well as over the 3 days before his admission. He had had vague abdominal pains in the past, but these had settled spontaneously after a day or so. The present episode of pain was initially central, but later became generalized. One loose motion was passed immediately on arrival in hospital. No ascaris worms were known to have been passed or vomited. One week before he came to hospital he had had a fever with loss of appetite. Antimalarials had been given and had abolished the fever, whereupon he had felt better.

On examination, the child looked ill; he had dry lips and his tongue was coated. He was pale and anxious and obviously in pain. The pulse was 116/min and regular. His temperature was 38 °C. Blood urea was 5·1 mmol/l; Na, 121 mmol/l; K, 3·2 mmol/l; Cl, 88 mmol/l; HCO_3, 21 mmol/l.

The abdomen was distended and did not move with respiration. There was tenderness in the right upper and lower quadrants and guarding was mostly in this area as well as in the left iliac fossa. Bowel sounds were absent. Rectal examination was unrevealing, only some loose faecal matter being present. Plain radiographs of the abdomen were unhelpful. A diagnosis of intestinal ascariasis was made and conservative management instituted. Review 4 h later did not reveal any change but re-examination at 8 h demonstrated evidence of increasing toxicity. The pulse was now 126/min and his temperature was 38·5 °C; abdominal guarding was now more marked. Laparotomy was decided upon.

The peritoneal fluid was bile-stained and purulent. A leaf of the greater omentum was seen to be involved in an attempt to circumscribe the focus of infection. A perforation approximately 1 cm in diameter lay at a point half-way between the mesenteric and the antimesenteric borders of the gut some 100 cm from the ileocaecal valve; its edges were quite regular. A single round worm lay among the coils of small bowel while two others tried simultaneously to escape from the small bowel lumen. Another perforation, approximately 4 mm in diameter, lay about 5 cm proximal to the larger perforation. From it, too, a round worm was in the process of completely freeing itself from the bowel lumen. Just proximal to the perforations lay the main mass of *A. lumbricoides*; 37 worms were removed from this segment of ileum.

The edges of the perforation were excised and sent for histological study. Peritoneal toilet was effected and the wound closed in layers. Tetracycline was given for 7 days only. Recovery was uneventful. The specimen was reported as showing non-specific acute inflammation.

Bacteriological studies of blood, stool and peritoneal pus were positive for proteus and *E. coli*. Blood and urine cultures were negative. The Heaf test was grade 1 positive. The Widal agglutination reaction was not significant.

Discussion

Ascaris lumbricoides is a common resident of the small intestines of man in the Tropics. All age groups are affected. In some regions up to 90 per cent of the children are infested. In Ibadan, Nigeria, a study of stool specimens at the University College Hospital during a 12-month period (1976–7) found the ova of *A. lumbricoides* in 840 cases out of 2400 sampled, an incidence of 35 per cent.

Human infection is acquired by accidentally ingesting the embryonated eggs from polluted drinking water, food or infected soil. Ingested eggs reach the duodenum where their shells are softened by intestinal juices, thereby freeing the larvae. Normally, the migrating larvae hatched from eggs produce no damage. It is the mature worms which damage the wall of the small intestine by processes at present unclear. Bowel suture lines may be penetrated (McNair, 1972) and minute orifices may be entered (ducts of Santorini and Wirsung, ampulla of Vater, the appendix) to cause various pathological lesions. Penetration of the healthy intact intestinal wall may be by trauma or enzymatic digestive processes. That perforation does occur in the worm-infested bowel entirely unassisted by typhoid ulceration or other pre-existent disease is suggested by a combination of clinical and laboratory evidence.

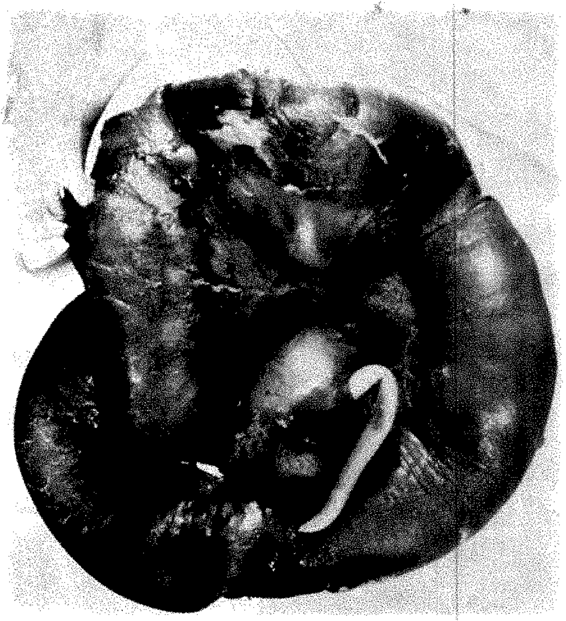

Fig. 1. *Ascaris lumbricoides* and perforation of the ileum.

Clinical

The history is short and prodromal symptoms are absent; if present they are indefinite and vague. Fever may be present in children due to the presence and activity of the worms, but the malaise, toxicity and prostration seen in typhoid fever are unusual.

Abdominal pain and vomiting are the main symptoms in uncomplicated cases. The abdominal pain is vague but may be colicky and is mainly epigastric (Swartzwelder, 1946). With perforation, the pain becomes generalized, so that the abdomen becomes full, distended and doughy. The firm, rigid abdomen and the typical facies seen in typhoid are not there. Bowel sounds may persist if spillage of ileal contents is prevented by the worms plugging the perforation and peritonitis is minimal. Vomiting occurs with obstruction by a worm bolus or the ileus secondary to peritonitis. Diarrhoea, if present, is due to spillage of ileal contents into the pelvis, although bolus obstruction by worms causes constipation, especially in children. The stool may contain worms, mucus or blood but lacks the pea-soup character of typhoid enteritis. Cachexia is rare in adult surgical cases. In children, it is associated with massive chronic infestation (Piggott et al., 1970). In such cases it is indistinguishable from the malnourished child with early typhoid perforation.

Abdominal radiographs may show the typical whirlpool pattern ('tourbillon'). With perforation subdiaphragmatic air may be seen, but this sign is indistinguishable from typhoid perforation with coexistent intestinal ascariasis.

The findings at laparotomy strengthen the case for a non-typhoid aetiology. The gut in early cases looks healthy. The perforations are usually rounded, the edges regular and not undermined. It may or may not be through a Peyer's patch and may be anywhere on the circumference of the small intestine. Typhoid perforation has a predilection for the antimesenteric border of the ileum. The lymphatic tissues, usually noted to be enlarged in typhoid fever, were not significantly enlarged in any of the cases reported. The greater omentum, that 'abdominal policeman', when fully developed, is present at the site of inflammatory reaction. In typhoid perforation this structure is conspicuously absent from the site of intestinal spillage and there is little fibrinous reaction, so that only the bowel loops are left to try to contain the spreading septic focus. Perforations may occur in any number; in the first case reported here, perforation was at six different sites.

The subsequent clinical course of the patients also supports an ascaris aetiology; the stormy postoperative course of the perforated typhoid case is unusual. The wound may be infected, as in our cases, but certainly not to the same degree as the extensive contamination and massive purulent discharge typical of typhoid perforation and which regularly initiates wound dehiscence and incisional hernia.

Laboratory data

Laboratory data assist greatly in excluding any pre-existent or concurrent disease. Microscopy and culture of peritoneal fluid, urine, blood and stool will confirm the presence of salmonella or other organisms. In the 3 cases reported above, salmonella was not isolated. The Widal agglutination reaction failed to show a significant rise in titre in any of the cases, and histopathological studies only demonstrated non-specific acute inflammatory reaction, with eosinophils in abundance at the sites of perforation. In the 2 cases sampled, the leucocyte count was within the normal range.

It is usual for at least one of the investigations to show the presence of salmonella. When the typical typhoid cellular pattern with aggregations of monocytes, basophils and lymphocytes are absent, one must search for other causes. The failure to demonstrate the presence of any of the recognized agents of ileal perforation does not necessarily implicate *A. lumbricoides* merely by their presence. Evidence of bowel wall damage by an active process of round worms is necessary to implicate them in perforation of the gut. Induration of the tissues around the perforation is a common finding, and ascaris worms are known to cause induration of the bowel wall by pressure, trauma and possibly by their toxic secretions. Advantage may also be taken of the rare, solitary, small ulcers of the small intestine. When ascaris worms are found lying freely in the peritoneal cavity and the tissue around the site of perforations is replete with eosinophil cells, the conclusion is very pressing.

It would seem from these observations that in some cases of distal ileal perforation, *A. lumbricoides* is the agent responsible. How this feat is achieved in the healthy bowel is at present conjectural; whether an enzymatic substance is secreted which dissolves the wall of the bowel or whether the worms merely take advantage of some wall weakness are two strong possibilities. Direct pressure with ulceration, necrosis and perforation would seem to be the most obvious mechanism.

It is suggested that in a patient with an acute abdomen, evidence of heavy infestation with *A. lumbricoides* makes a diagnosis of intestinal perforation more likely.

Surgical aspects of radiation injury to the intestine

R. B. GALLAND AND J. SPENCER*

SUMMARY

The clinical features are described of 37 patients requiring surgical management for radiation injury to the intestine sustained as a result of treatment of abdominal or pelvic malignancy. Twenty-nine of the patients underwent operation and only 4 remained symptom-free after the procedure. Thirteen patients died in the postoperative period, and of these, 5 were free of the original disease. Possible predisposing factors in the production of intestinal injury are discussed, as are various means of dealing with the established condition.

THE advent of radiotherapy for pelvic and abdominal malignancy has produced dramatic amelioration of many diseases, but at the cost of a wide range of gastrointestinal side effects. These may range from a mild proctitis, causing little or no problem, to a more severe injury that results in the death of the patient whilst there is an apparent 'cure' of the original disease. The incidence of these complications is difficult to assess; if one includes all gastrointestinal symptoms, it would appear to be 50–75 per cent (Maas, 1948); however, the incidence of those requiring operation ranges from 2 to 17 per cent (Aldridge, 1942; Requarth and Roberts, 1956).

This paper presents the clinical details of a series of patients who required surgical management as a result of previous radiotherapy. Malabsorption, uncomplicated enteritis, colitis and proctitis, none of which is normally managed by a surgical unit, are, therefore, not included.

Patients and methods

Thirty-seven patients, 30 women and 7 men, were included in the study. All presented for management between 1960 and 1977 inclusive. At the time of their initial radiotherapy, the age range of the women was 38–80 years (mean 54 years) and that of the men 17–67 years (mean 53·3 years).

Initial pathology

The lesions for which radiotherapy had been required are listed in *Table I*. It can be seen that the women had mainly gynaecological tumours, whereas 5 of the 7 men had cancer of the bladder.

Radiotherapy

All patients received conventional external radiotherapy, combined in the case of the cervical lesions with radium implants. During radiotherapy, 24 of the 37 patients (64 per cent) developed some form of gastrointestinal disturbance, as shown in *Table II*. As may be seen, diarrhoea was the commonest problem, occurring either alone or combined with anorexia, vomiting or abdominal pain in 21 of the 24 cases.

In the majority of these patients the condition settled on symptomatic treatment, but 4 patients required emergency operations, 3 for peritonitis and 1 for large bowel obstruction.

Timing of gastrointestinal presentation

The latent period, from the time of radiotherapy to presentation, varied greatly, small bowel lesions tending to present later than large bowel lesions, as seen in *Fig.* 1. The latent period for small bowel presentation was 0–18 years (median 2 years 11 months), whilst that for the large bowel was 0–13 years (median 1 year 4 months). This difference is significant at the 5 per cent level (Mann–Whitney U test).

Fig. 2 shows the latent period of presentation for each lesion. Perforation tended to present earliest, the range being 0–6 years (median 6·5 months). Three cases presenting with this condition did so during the course of radiotherapy. Fistula formation was seen between 8 months and 6 years 9 months (median 21 months) and haemorrhage between 3 months and 2 years 6 months (median 23 months). Stricture formation had the longest latent period, the range being 0–18 years (median 27·5 months). The difference between the times of presentation of perforation and stricture was significant at the 5 per cent level, using the Mann–Whitney U test.

Gastrointestinal injuries sustained

The manner of presentation varied with the type of lesion subsequently identified, the latter being shown in *Table III*. Of the 37 patients studied, 23 patients had only one lesion and 14 had multiple lesions. Multiple lesions were noted at the original presentation in 8 patients, and a further 6 patients developed second or third lesions after an interval.

A total of 54 separate lesions was noted, with almost equal numbers occurring in the large and small bowel. The commonest lesion seen was that of stricture formation, there being almost equal numbers of fistulas, perforations and cases of gastrointestinal bleeding. Of the small bowel fistulas, those of the mid-ileum were to the colon and the vagina respectively; those of the terminal ileum were to the bladder and to a chronic abscess cavity. The large bowel fistulas were to the bladder (3) and ileum from the sigmoid colon, and to the vagina (2) and the uterus from the rectum.

Diagnosis

The diagnosis of the lesions was, in most cases based on clinical grounds, though often confirmed radiologically. Biopsy, particularly in the case of the rectal and some of the sigmoid lesions, was also helpful. All tissue removed was sent for histological examination and was diagnosed as having features characteristic of radiation damage.

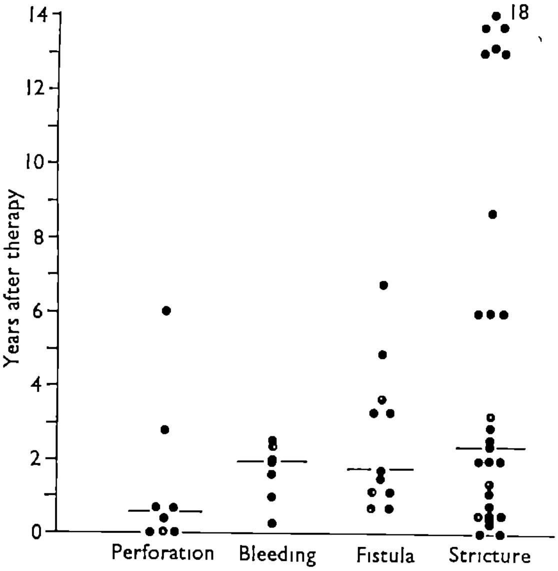

Fig. 2. Time of presentation of the various lesions encountered after radiotherapy. (Bars represent medians.)

Management

Management of these patients was conservative whenever possible in all except the 4 patients requiring urgent operative treatment during their course of radiotherapy. All but 8 patients, however, eventually came to operation. Of those 8 patients, 3 had ileal strictures diagnosed on barium follow-through examination, 3 had bleeding rectal ulcers that eventually healed and 2 had vesicocolic fistulas and died of renal failure before an operation could be performed.

Table IV shows the operations performed for the upper gastrointestinal lesions. The course in those who underwent

[illegible] small bowel a[illegible] noted that the mortality in this group was 8[illegible] cent) and that 3 of the patients who died were [illegible] to be free of tumour.

Similarly, *Table V* shows the large bowel op[illegible] taken. Two of the 5 primary anastomoses [illegible] th[illegible] patelnts died; a further patient having a Hartma[illegible] re[illegible] also died postoperatively of sepsis. Two of the [illegible] died were free of tumour. Of the 10 patients wh[illegible] tioning loop colostomies, 4 required reoperation [illegible] at the stoma.

Thus, of the 29 patients requiring surgery, 13 (45 per cent) subsequently died, of whom 5 were free of the original disease. Of those patients surviving surgery, only 4 remained totally free of gastrointestinal symptoms on subsequent follow-up.

Past medical history

All but 10 patients had factors in their past medical histories which may be relevant. *Table VI* shows that the commonest factor was a previous operation. Six patients had suffered some form of cardiovascular disease and 3 had had previous pelvic sepsis. In several patients more than one factor was in evidence.

Finally, 7 of the 37 patients had severe radiation cystitis, 1 requiring cystectomy, while 1 patient had a radiation myelopathy and 1 had malabsorption.

Discussion

The effect of ionizing radiation on the gastrointestinal tract is twofold. First, there is a direct effect on the gut wall itself (Quastler, 1956), occurring during or shortly after the course of radiotherapy, and secondly, there is a progressive obliterative vasculitis (Warren and Friedman, 1942) which may produce ischaemic intestinal problems many years after treatment.

In our series, the earlier presentation of perforation compared with stricture ($P < 0.05$) suggests that the former is due mainly to the direct effect on the gut wall, ischaemia being relatively more important in the case of stricture formation. Haemorrhage and fistula formation appear to occupy an intermediate position.

One would expect the vasculitis effect to be enhanced by arterial insufficiency due to any other cause. De Cosse et al. (1969), when comparing 100 patients suffering from radiation injury with 227 consecutive uninjured treated patients, found that hypertension, diabetes and cardiovascular disease were all significantly more common in the injured group. In our series 6 patients were regarded as having significant cardiovascular disease, 4 of these being hypertensive; no patient had diabetes mellitus.

Other factors that have been regarded as important in inducing radiation injury are excessive radiation dosage and previous operation or sepsis.

Excessive radiation has been mentioned as a possible causative factor in the production of intestinal injury. Jackson (1976) stated that 21 per cent of 52 patients in his series were subjected to high or very high doses. Only 3 of the 37 patients were regarded as having excessive radiation, however, and in each case, this was due to further courses of treatment undertaken in an attempt to eradicate recurrence of the original tumour.

The role of previous abdominal operation or sepsis and the subsequent adhesion formation is uncertain; theoretically at least, adhesions, by immobilizing the intestine, may increase the likelihood of any one section of bowel receiving too high a dose of radiation (Localio et al., 1969; Maruyana et al., 1974). De Cosse et al. (1969), however, found that only previous hyste[illegible] predisposed to radia[illegible]jury when [illegible]elvic [illegible]therapy [illegible] being considered, other [illegible]dominal operations and previous sepsis apparently [illegible]levant. Green et al. (1975), performing [illegible] barium followthrough examinations, [illegible] relationship between relatively [illegible] previous operations.

[illegible] terminal ileum, ascending colon [illegible] and rectum are relatively fixed, it is difficu[illegible]ow formation of adhesions could immobilize [illegible]ther. However, adhesion formation may be [illegible] more important in the jejunum and mid- and [illegible]um. In our series, 22 of the 37 patients had undergone previous operations, 16 of these patients requiring operation for the presenting malignant disease. All of the 11 patients in whom 14 lesions of the jejunum, mid-ileum or transverse colon subsequently developed had undergone previous operation.

The diagnosis of radiation injury should always be considered in patients who have had previous radiotherapy and who present with abdominal symptoms. The latent period was as long as 18 years in 1 patient in this series and it is clearly important not to misdiagnose patients presenting with abdominal problems as having secondary malignancy.

A review of the surgical management of radiation injury to the small intestine has recently been published (Swan et al., 1976). Twenty-eight series produced 199 patients and a further 45 patients were added by the authors themselves. In the original 199 patients, the mortality was 21 per cent for those having a resection with primary anastomosis and 10 per cent for those having the lesion bypassed, the anastomotic leakage rate being 36 per cent and 6 per cent respectively. Similarly, in their own series of 45 patients, there was a mortality of 53 per cent and 7 per cent for the resection and bypass groups respectively, anastomotic leakage rates being 65 per cent and 11 per cent.

In our series, 8 of 18 patients having a resection and primary anastomosis of the small bowel developed an anastomotic leak and 1 patient developed a perforation proximal to an intact anastomosis. Of these 9 patients, only 1 survived. Of the 2 patients having a bypass, neither anastomosis leaked and both patients survived. These figures suggest that even though bypass surgery may theoretically result in a subsequent 'stagnant loop' syndrome, it may be preferable to resection with a primary anastomosis. Should resection and anastomosis be undertaken, wide resection is advisable since the extent of the bowel damage is often much greater than expected (Wellwood et al., 1974).

In our series, 1 patient developed peritonitis caused by a perforation 12 cm proximal to an intact anastomosis, the bowel being diseased histologically although macroscopically normal at the original laparotomy.

A temporary loop jejunostomy or ileostomy may be used to cover the anastomosis (Jackson, 1976).

Similarly, in colonic lesions, simple procedures fared better than more radical operations. None of the 10 patients who had defunctioning colostomies died, in contrast to 2 out of 5 patients who died after resection and primary anastomosis.

With the generally unsatisfactory results of surgical management of patients with radiation injury to the gut, avoidance of the problem is clearly the ideal. At-risk groups appear to be identifying themselves, these being those patients having had previous pelvic operations or sepsis, those having cardiovascular problems or diabetes mellitus and also the group of thin, elderly, female patients shown by Green et al. (1975) to have a deep pelvis, containing a greater amount of small intestine than usual. Modification of the usual radiotherapy technique may be needed for all these patients, who also require careful long term follow-up.

Thyroid cancer in Kuwait: review of 117 cases*

K. A. EL-GHAMRAWI AND M. S. KHALIFA†

SUMMARY

One hundred and seventeen patients with thyroid cancer were seen at the Radiotherapy and Isotope Centre, Al-Sabah Hospital, Kuwait, between 1963 and 1974. Thyroid cancer constituted 4·7 per cent of all cancer cases among females and 2·4 per cent among males. Of these carcinomas, 58 per cent were papillary, 25 per cent follicular, 11 per cent anaplastic and 1·7 per cent medullary. Four cases (3·4 per cent) were of malignant lymphoma. The 10-year survival was 74, 96 and 21 per cent for papillary, follicular and anaplastic tumours respectively. The present series confirms the prognostic value of age, sex and histology and shows that node metastasis does not prejudice survival. The study does not show any correlation between the type of operation and survival.

THYROID cancer differs from many other neoplasms in that incidence and type differ widely in various geographical areas (Waterhouse et al., 1976). It is noted that among females in Kuwait, carcinoma of the thyroid is the second commonest type of cancer (Omar and El-Ghamrawi, 1976) and represents the commonest form of head and neck tumour (Parikh and El-Ghamrawi, 1977).

This relatively high frequency has stimulated this review of the cases managed since 1963. This series represents all cases of thyroid cancer diagnosed in Kuwait during this period, as there is a general agreement with surgeons to refer all cases to us for postoperative treatment. Some cases may have been missed during the earlier period of the study, before the establishment of the Cancer Registry in 1971.

Patients

During the period of the study we had on our records 117 cases of thyroid cancer, of which 69 were females and 48 were males, a sex ratio of 1·4 : 1. These cases represented 4·7 per cent of all female cancer patients and 2·4 per cent of all male cancer patients.

The mean age for females was 42 years±14·0 standard deviation, and for males, 49±20. No difference was observed in the mean age between Kuwaitis and non-Kuwaitis. The age-corrected incidence for different age groups is shown in *Figs.* 1 and 2 for females and males respectively.

All patients except 6 had histopathological confirmation of the presence of tumour and were subdivided according to the World Health Organization classification (Hedinger and Sabin, 1974). These 6 patients were elderly, refused surgery and the diagnosis was clinically certain. Needle biopsy was not then our common practice.

Results

Papillary carcinoma was the commonest (58 per cent) of the tumours, followed by follicular (20 per cent) and anaplastic (11 per cent) (*Table I*). Papillary and follicular carcinomas were more frequent during the third and fourth decades of life. Anaplastic tumours were commonest during the seventh and eighth decades.

The common clinical presentations are shown in *Table II*. Goitre was the commonest presentation (81 per cent).

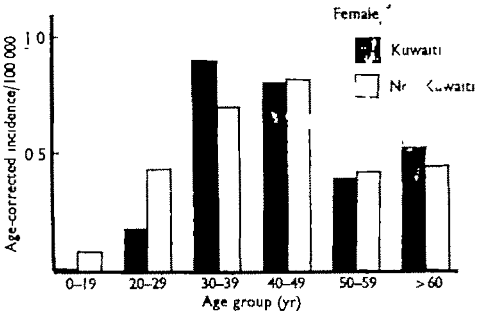

Fig. 1. Age corrected incidence for females.

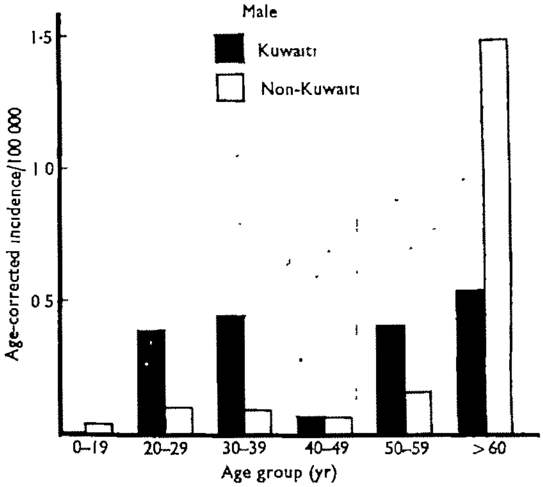

Fig. 2. Age-corrected incidence for males.

All cases with confirmed histology were retrospectively staged according to the TNM system recommended by the International Union Against Cancer (UICC, 1974). The relation of clinical staging to histology is shown in *Table III*. Over 50 per cent of patients presented at early stages T1–2 N0.

Towards the end of this study there was a trend towards more radical surgery (total and subtotal thyroidectomy), but neither histology nor the stage of the primary tumour seemed to influence the type of operation performed.

Thirty-eight patients (32·5 per cent) had palpable cervical nodes. Ten had block dissection, 15 total excision of palpable nodes, 5 excision biopsy and 6 no surgery to palpable nodes.

Postoperative adjuvant irradiation was given on 70 occasions (10 patients received deep X-ray and 60 had cobalt teletherapy). Sixty-three patients received therapeutic doses of radioactive iodine with or without external irradiation. Two cases with advanced metastatic disease received chemotherapy (Velbe and Endoxan). All the patients were kept on either replacement hormonal therapy (Eltroxin 150 µg daily) for undifferentiated tumours or high suppressive doses (Eltroxin 300 µg daily) for differentiated tumours.

Survival was calculated from the date of definitive treatment to 31 December 1976. Survival curves were computed using the actuarial method (Berkson and Gage, 1950). Difference in survival between the various groups was tested using the χ^2 test at a confidence level of 0·05. We analysed our results according to various factors known to influence prognosis: these are age, sex, histology, cervical adenopathy and type of surgery. Ten-year survival was 71 per cent: females did significantly better than males—74 per cent survival versus 64 per cent. Younger patients had a significantly better prognosis, probably because of the influence of histology. Follicular and papillary tumours were associated with a significantly better prognosis than anaplastic tumours (*Fig.* 3). Neither the presence of positive nodes nor the type of surgery was found to influence prognosis significantly. This could be explained by the fact that the majority of our patients received postoperative irradiation, which may have improved the expected poorer results following conservative surgery and in those with metastatic nodes.

Twenty-nine patients were known to have died during the period of the study. The commonest cause of death was the primary disease, which accounted for 76 per cent of the deaths (*Table IV*). Anaplastic carcinoma was the most fatal histological type (*Table V*).

Discussion

Kuwait has a peculiar population composition: 47 per cent are Kuwaiti, 42 per cent are non-Kuwaiti Arabs and only 11 per cent are non-Arabs. Fifty-seven per cent are male and 43 per cent female. Eighty-six per cent are below the age of 40. In Kuwait the incidence of thyroid cancer is 2·8 females and 1·9 males per 100 000 of the population. This is a higher incidence than the 1 per cent reported from non-endemic parts of the world (Waterhouse, 1974; Staunton and Greening, 1976). There is no significant difference in the age-corrected incidence of thyroid cancer among Kuwaiti and non-Kuwaiti females (*Fig.* 1), whereas thyroid cancer is more common among Kuwaiti males below the age of 60 and more common among non-Kuwaiti males above 60 years of age (*Fig.* 2).

The aetiology of thyroid cancer is not always clear, but certain factors associated with a high frequency of thyroid tumours have been described, such as accidental irradiation during childhood (Duffy and Fitzgerald, 1950; Winship and Rosvoll, 1961; Modan et al., 1974; Wade, 1975), a prolonged high level of thyroid-stimulating hormone (TSH) (Purves and [illegible] ...cer is common. Criteria [illegible] benign from malignant non- [illegible] have been defined (Hurxthal and Heine- [illegible] 958; Suakal, 1959). The incidence of cancer in apparently benign goitre varies between 9 and 66 per cent (Hurxthal and Heinemann, 1958; Till, 1965; Campbell and Sage, 1975). The corresponding figures for solitary nodules vary between 2·7 per cent (Campbell and Sage, 1975) and 33 per cent (Cattell and Colcock, 1953). In the present retrospective survey attempts to estimate the incidence of solitary nodules from the patients' files were difficult and inaccurate. It is known that only 50 per cent of clinically solitary nodules are truly solitary (Taylor, 1969).

Any discussion of the results of treatment of thyroid cancer must take into consideration the prognostically significant characteristics of any series, such as age, sex and histology (Sloan, 1954; Halnan, 1966, 1975) and the long natural history of many tumours. Therefore, every series is unique. Evaluation of treatment must consider also the extent of thyroid resection, treatment of metastatic nodes and the value of postoperative external irradiation and of radioactive iodine. In papillary carcinoma, total thyroidectomy is favoured by many surgeons (Hirabayashi and Lindsay, 1961; Clark et al., 1966) because 80 per cent of papillary tumours are multifocal and spread in both lobes (Russel et al., 1963). Owing to the high morbidity of total thyroidectomy, however, subtotal thyroidectomy is becoming more popular (Staunton and Greening, 1976; Woolner et al., 1976) except where a gross lesion indicates total thyroidectomy. In follicular carcinoma total thyroidectomy has been recommended (Staunton and Greening, 1976) because of the poor results of less radical surgery. Our study, on the contrary, showed good results for follicular carcinoma (*Fig.* 3). Undifferentiated (anaplastic) carcinoma raises different problems. The majority of tumours present when advanced and radical surgery is impossible. Most authors advocate complete tumour removal and subsequent external irradiation.

The problem of metastatic nodes is of particular importance in papillary tumours. Crile (1957) advocated individual removal of metastatic nodes. Most recent studies have shown that radical dissection gives better results than conservative node surgery (Woolner et al., 1961; Franssila, 1971; Lindahl, 1975; Staunton and Greening, 1976). In our series neither the type of surgery nor the presence of node metastases influenced prognosis significantly. This may be due to the aggressive postoperative radiotherapy given to the majority of patients. However, assessment of the value of adjuvant irradiation presents difficulties as it often forms one part of a combined plan of treatment. Most advanced inoperable cases are treated by radiotherapy and there is no controlled clinical trial comparing the

[illegible] ation [illegible] Haln [illegible] y ca [illegible] e i [illegible] nt [illegible] who [illegible] t receive adju[illegible] in pa[illegible] who had postop[illegible] pract[illegible]. The value of postop[illegible] anaplastic tumours is universall[illegible] are still poor. The value of radica[illegible] metastatic disease and for differentiated [illegible] combination with surgery, has be[illegible] repeate[illegible] (Smithers, 1951; Halnan, 1969; Pochin, 1971; [illegible] 1975).

In our present practice we depend more o[illegible] sive radioiodine therapy, together with suppre[illegible] high doses of Eltroxin adjusted by repeated T[illegible] estimation, in the initial treatment of papillary a[illegible] follicular carcinoma and on multiple chemotherap[illegible] with supervoltage for anaplastic tumours.

ACHALASIA OF THE CARDIA

H. R. S. HARLEY, MS, FRCS, *Consultant Cardiothoracic Surgeon, Llandough Hospital, Penarth, Glamorgan.*

Contents: Morbid Anatomy and Histology; Aetiology; Clinical Features; Radiological Examination; Oesophagoscopy; Carcinoma of the Oesophagus; Respiratory Complications; Joint Complications; Surgical Treatment; Results of the Modified Heller's Operation; References; Index.

In this book coverage of the physiological and radiological abnormalities of the oesophagus is given, differential diagnosis is discussed at length and the importance of motility studies to a proper understanding of this and other diseases of the oesophagus is stressed. While this book is concerned primarily with achalasia of the cardia, upsets of motility of the oesophagus due to other causes, such as diffuse oesophageal spasm, presbyoesophagus, reflex oesophagitis and progressive systemic sclerosis, are given careful consideration.

216 × 138 mm, 180 pages, 83 illustrations.   UK net price £10·00

Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, Broadmead House, 21 Panton Street, London SW1.* Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the Journal unless rights are reserved before publication. Original illustrations must be securely packed and protected.

Business communications should be sent to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery. Advertisements:* All communications should be addressed to *Hexagon Publishing Co. Ltd., 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone 0727 60641: telex 21827).

Manuscripts
Two good quality plain paper photocopies of all written and tabular material should be submitted and the original retained by the author. Illustrations should also be submitted in duplicate clearly marked on the back to show number, orientation and author. Legends should be typed on a separate sheet. For halftones, unmounted glossy photographs or positive prints (not X-ray negatives or slides) are required. Colour prints should be accompanied by the original transparencies; a contribution to the cost of reproduction is always necessary. Drawings must be ready for reproduction: a leaflet giving details of the preparation of artwork is available from the publishers and must be consulted. Tables are typed on separate sheets and must have a Roman identifying number plus a short descriptive heading.

Presentation of statistics
Authors are reminded that: (*a*) the methods section of a paper should contain a mention of any statistical technique used: if the method is new or unfamiliar either a reference should be given or a description included as a brief appendix; (*b*) if alternative techniques could have been applied to the data, a short justification of the method is often appropriate; (*c*) in clinical trials, the confidence or tolerance limits of the results should be quoted, particularly when formal statistical significance at the 5 per cent level is only just reached; (*d*) abbreviations for statistical terms should follow those used in *Documenta Geigy Scientific Tables*, 7th edition, 1970.

SI units
It is Journal policy to use SI units except for measurement of blood pressure where mmHg is preferred. Authors should consult: Baron D. N., Broughton P. M. G., Cohen M. et al. (1974). The use of SI units in reporting results obtained in hospital laboratories. *J. Clin. Pathol.* **27**, 590–597. Reprints are available from British Medical Association, London.

References
The citation of references is by the Harvard system, a detailed description of which can be obtained from the Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE. Briefly the name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. More than two authors may be indicated in the text citation by 'et al.'. More than three authors may be indicated in the list of references by 'et al.'. The style of author and journal references should conform with the *Index Medicus:* sequence of referencing is author(s), year of publication, title of article, name of journal, volume number, first and last page numbers.

A reference to a book should give in order: the names and initials of all authors, editors or compilers, date of publication, title of book, edition number, place of publication, publisher's name, first and last page numbers of the contribution.

A more detailed list of instructions is published yearly in the January issue.

Danol

danazol

controls pituitary gonadotrophins without exerting oestrogenic or progestogenic activity

WINTHROP

For the treatment of endometriosis, infertility associated with endometriosis, fibrocystic mastitis, virginal breast hypertrophy, gynaecomastia, primary constitutional precocious puberty and other similar endocrine disorders where control of the release of pituitary gonadotrophins LH and FSH would be of therapeutic value.
Danol (danazol 200 mg). PL 0071/0095. Bottles of 100 capsules. Basic N.H.S. cost of one day's treatment £1.42 (3 capsules).
Danol-½ (danazol 100 mg). PL 0071/0094. Bottles of 100 capsules. Basic N.H.S. cost of one day's treatment 72 p. (3 capsules).
Dosage. Adults 200-800 mg daily, children 100-400 mg daily. See Data Sheet for details.
Contra-indications: Pregnancy.
Precautions. 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop.
Side Effects. Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control.
Danol is a trade mark. Further information available from:– Winthrop Laboratories Surbiton-upon-Thames Surrey KT6 4PH.

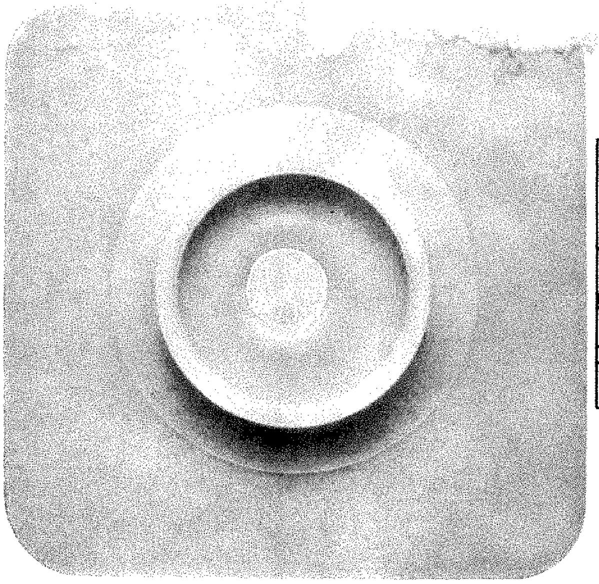
Surgicare^{TM} System 2 saves the daily trauma of peeling off adhesive bags often resulting in irritation, soreness and discomfort. The Stomahesive^{TM} with Flange can be left on the skin undisturbed for several days whilst pouches are replaced as often as necessary... so simply.

Kinder to the skin

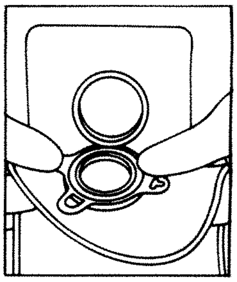
Stomahesive^{TM} with Flange may be used by patients who have experienced sensitivity reactions when using ordinary adhesives and karaya or where perspiration under the adhesive is a regular source of irritation and discomfort

Unequalled comfort

The Stomahesive^{TM} base will mould to irregular contours of the skin and is so easy to apply without wrinkling. Comfort is derived not only from the feel of Stomahesive^{TM} against the skin but from the confidence that the appliance will be secure and leak free irrespective of the condition of the skin.



n the Stomahesive flange remaining undisturbed, pouches may be removed and replaced as necessary.



The colostomist, for example, may change pouches several times a day without the need to disturb the Stomahesive^{TM} base and its flange.

A prospective randomized trial of vagotomy in chronic duodenal ulceration

C. G. KOFFMAN, J. B. ELDER, I. E. GILLESPIE, P. C. GANGULI, D. G. OSTICK, D. J. COWLEY, I. W. DYMOCK, D. E. F. TWEEDLE, P. F. SCHOFIELD, C. D. R. PENGELLY, M. SHAFIQ, D. R. SHREEVE AND M. PALMER

SUMMARY

In a prospective, randomized trial, 76 patients with duodenal ulceration treated by truncal vagotomy and pyloroplasty were compared with 77 patients who underwent highly selective vagotomy. A total of 149 patients was followed up for from 1 to 4 years, the average follow-up period being 2·6 years. There was no operative mortality and no significant difference in postoperative morbidity between the two groups. The incidence of recurrent ulceration was greater after highly selective vagotomy, but this difference was not statistically significant. The clinical results were comparable in each group, and although the incidence of diarrhoea and dumping was greater after vagotomy and pyloroplasty, this difference was not statistically significant.

TRUNCAL vagotomy and pyloroplasty (TVP) is currently the operation most commonly performed in the treatment of chronic duodenal ulceration in Great Britain (Johnston and Goligher, 1976). The reported operative mortality is lower than for gastrectomy operations but the recurrent ulcer rate is higher (Goligher et al., 1968).

Highly selective vagotomy (HSV), also described as parietal cell vagotomy or proximal gastric vagotomy, was initially conceived by Griffith and Harkins (1962) and introduced clinically with a drainage procedure by Holle and Hart (1967), and without a drainage procedure by Johnston and Wilkinson (1970) and Amdrup and Jensen (1970).

Amdrup et al. (1974) suggested that HSV gave better clinical results than vagotomy and drainage operations, chiefly by decreasing the incidence of diarrhoea and dumping. They also reported a low recurrent ulcer rate of less than 1 per cent in over 300 patients followed up for 2–4 years in Leeds and Copenhagen, whereas other authors (Grassi et al., 1973; Wastell et al., 1974; Kronborg and Madsen, 1975) have observed a recurrence rate of between 1 and 22 per cent.

Consequently, several trials have been set up to compare HSV with other forms of vagotomy and drainage. A prospective, randomized trial of HSV and TVP in Sheffield (Koffman et al., 1975) showed a recurrent ulcer rate of 2·5 per cent in each group of 40 patients followed up for 1–3 years. There were comparable clinical results but there was significantly more diarrhoea after TVP. Kennedy et al. (1975) reported that HSV produced significantly less dumping, nausea and bile vomiting than selective vagotomy and gastrojejunostomy without an increased risk of recurrent ulcer (2 per cent in each group).

More recently, Amdrup et al. (1977) have compared HSV and selective gastric vagotomy without drainage in a randomized trial in which 267 out of 554 patients were followed up after 2 years. The recurrence rates were 8 per cent in each group and there were similar clinical results, although there was significantly less dumping after HSV. We considered that it was important to carry out a prospective, randomized comparison of the most commonly used operation, TVP, with HSV in a trial encompassing not only teaching hospitals but also district general hospitals.

Patients and methods

Design of the trial

A group of physicians and surgeons from four hospitals in the Manchester area took part in this trial. Both male and female patients undergoing surgery for proved chronic duodenal ulceration were entered into the trial between 1973 and 1976. All patients were assessed preoperatively using a standard questionnaire. Fifty-eight per cent of patients seen during the trial period were excluded for the following reasons.

1. Emergency operation for perforation or bleeding.
2. Pyloric stenosis.
3. Concurrent gastric ulcer.
4. Associated gastrointestinal disease such as biliary tract disease and symptomatic hiatus hernia.
5. Hypergastrinaemia.
6. Either operation not technically feasible at laparotomy.

After the diagnosis of chronic duodenal ulceration had been confirmed at laparotomy, patients were randomly assigned to either HSV or TVP by the drawing of a trial card from a box

kept in the theatre. The two operations were standardized as far as possible. HSV was performed using a technique described by Johnston and Wilkinson (1970), as follows: (*a*) each nerve of Latarjet was identified and vagotomy was begun at approximately 6 cm from the pylorus along the lesser curvature; (*b*) the anterior and posterior leaves of the lesser curvature were divided between the stomach and nerve of Latarjet separately; (*c*) the lower oesophagus was encircled and all vagal fibres surrounding it were divided.

Truncal vagotomy and Heineke–Mickulicz pyloroplasty was standardized in the following way: (*a*) a portion of each vagal trunk was sent for histology; (*b*) the pyloroplasty was made 6–8 cm long and closed in one or two layers with chromic catgut.

The preoperative investigations, operative findings and early postoperative progress were recorded by the surgeons on standard forms. On the tenth postoperative day the volume of fasting gastric juice was measured in 54 per cent of the patients. This included all patients admitted to the trial from one district general hospital and one teaching hospital.

Follow-up was carried out at 1 month by the surgeon, and then at 3, 6 and 12 months and thereafter at 6-monthly intervals by a member of the team who did not know the nature of the operation. A detailed assessment of specific symptoms such as pain diarrhoea and dumping was made and recorded using a standard form. An overall assessment of the clinical result was made independently by one physician using a modified Visick classification: grade 1, an excellent result with no gastrointestinal symptoms; grade 2, some mild symptoms but the patient is happy with the result; grade 3, more severe symptoms causing some disability but still better than the preoperative condition; grade 4, recurrent ulceration or disability as severe as or worse than before the operation for any reason.

All information from the standard form was transferred to punch-cards and analysed by computer, using a package of statistical programmes (Statistical Package for the Social Sciences).

Patients

A total of 153 patients has been entered into the trial and followed up for a minimum of 1 year (*Table I*): 76 patients underwent TVP and 77 HSV. The two groups were comparable in the distribution of age and sex. The preoperative data for the two treatment groups were compared and, of 150 variables tested, only previous perforations and duodenal ulcers in first-degree relatives were significantly more frequent ($P < 0{\cdot}05$) in the HSV group, whereas preoperative bile reflux and bile vomiting were more frequent ($P < 0{\cdot}05$) in the TVP group. This incidence of difference is no more than would be expected by chance alone.

Follow-up

In all, 149 patients were seen for follow-up between 1 and 4 years (mean 2·6 years) after operation (*Table II*). One patient died 4 months postoperatively from myocardial infarction and 3 patients have been lost to follow-up.

Results

Immediate

There was no operative mortality. Chest infections were common after both operations (*Table III*) but the difference was not statistically significant. Sixteen patients had chest infections after TVP, whereas there were 20 after HSV. Two patients from each treatment group had pulmonary emboli, which were recognized clinically. The number of wound infections was the same after each operation, namely 6 patients from each group, but 3 of the patients in the TVP group were found subsequently to have incisional hernias. There were no incisional hernias after HSV.

On the tenth postoperative day 83 patients underwent nasogastric intubation and aspiration of residual gastric juice following an overnight fast. There was a significantly greater residual volume in the TVP group ($P < 0{\cdot}01$) (*Table IV*).

One patient from each treatment group developed other major complications. After TVP 1 patient had a prolonged ileus and after HSV 1 patient had a large gastrointestinal bleed. The mean length of stay in hospital was similar following both operations; 10·7 days after TVP (range 6–19) compared with 10·9 days after HSV (range 5–30).

Long term

Twelve patients had suspected or proved recurrent duodenal ulcers: 9 of these patients were from the HSV group and 3 from the TVP group (*Table V*). The incidence of proved recurrent ulcer after HSV was 8 per cent and after TVP 4 per cent. The proved recurrent ulcers had been identified on barium meal examination and gastroscopy or seen at a second operation. In the suspected group either these investigations had not been performed at the time of writing or the results were equivocal.

An overall assessment of functional results was made using a modified Visick classification. Grades 1 and 2 were considered to be good results and grades 3 and 4 were considered poor (*Table VI*). The results for the two operations were similar: 63 patients were considered to have good results after TVP compared with 61 patients after HSV, whereas 11 and 14 patients respectively had poor results.

Dumping (defined as the presence of two or more of the following symptoms: faintness, sweating, fatigue or fullness after food) was present in 7 patients after TVP compared with 3 patients after HSV. This difference is not statistically significant. All patients were asked about bowel habit, and specifically about the usual character of the stools, the number per week and the patient's impression of bowel habit. If the patient had diarrhoea, further questions were asked about the frequency and length of attacks, the number of motions passed in attacks and whether they were episodic. Five patients complained of diarrhoea after TVP but only 2 patients did so after HSV. When we compared the frequency of bowel habit at *follow-up* with the patient's bowel habit *before* operation we found little difference between the two operations. Although some patients had more frequent bowel action (24 after TVP compared with 18 after HSV), in the majority it was unchanged (40 and 45 patients respectively) and some patients had a less frequent bowel action (10 after TVP and 12 after HSV).

Discussion

This study was designed to compare two operations in uncomplicated duodenal ulceration and therefore required strict conditions for entry. Adherence to the stringent protocol required to achieve this uniformity resulted in the exclusion of 58 per cent of patients undergoing surgery. Randomization resulted in two groups which are very similar in that they are comparable in 146 out of the 150 variables recorded. Four hospitals took part in the trial, two being district general hospitals and two teaching hospitals.

There was no operative mortality and the immediate morbidity after operation was similar in the two groups. There was no statistically significant difference in the incidence of respiratory complications despite operating times 20–100 per cent longer for HSV than for TVP. A possible advantage of HSV is that the gastrointestinal tract is not opened and so wound contamination should not occur. However, the number of wound infections was the same after each operation, although there were 3 patients with incisional hernias after TVP.

One patient had a prolonged ileus with gastric stasis after TVP and it is interesting that we found a significantly larger volume of resting gastric juice after TVP on the tenth postoperative day, although this did not present a serious clinical problem. There have been reports of lesser curve ischaemia and necrosis (Newcombe, 1973; Halvorsen et al., 1975); however, following HSV no patient developed necrosis of the stomach in the present study. One patient did have a large gastrointestinal haemorrhage after HSV, but the cause of this was not established.

The number of patients with proved recurrent duodenal ulceration after HSV is higher than in the non-randomized series reported by Amdrup et al. (1974) but identical to the recent findings of Amdrup et al. (1977) in their randomized trial. The high recurrent ulcer rate reported by Kronborg and Madsen (1975) suggests a basic difference in clearance of the oesophagus, as suggested by Goligher (1974). We found a higher recurrence rate after HSV, although this was not statistically significant. This higher recurrence rate could be due to the limited experience of surgeons in performing the operation of HSV. However, all the principals in the trial had been to Leeds to watch demonstrations of the technique of HSV and had performed the operation during the 12 months before the trial.

According to the modified Visick grading used, 85 per cent patients had good results after TVP and 81 per cent after HSV. These results are similar to those of a smaller Sheffield trial (Koffman et al., 1975) in that there was no statistically significant difference in the number of good results after either operation.

A reduced incidence of both dumping and diarrhoea has been widely reported after HSV compared with TVP (Humphrey et al., 1972; Johnston et al., 1972; Koffman et al., 1975). Our results show a similar trend but in neither case does the difference reach statistical significance. The diarrhoea which patients suffered after TVP was usually episodic but when we compared the frequency of bowel motion before operation and at follow-up there was little difference between the two operations. Further detailed analysis of both preoperative and postoperative symptoms such as diarrhoea and dumping has been made by the Manchester Ulcer Trial Group (Koffman and Ostick, 1978) and will be reported fully in a subsequent paper.

From our results we can conclude that both HSV and TVP are safe operations and relatively free from complications. At this stage our results do not show a significant advantage for either operation with regard to recurrent ulceration, overall clinical results or postoperative diarrhoea and dumping.

Interrelations between serum gastrin levels, gastric emptying and acid output before and after proximal gastric vagotomy and truncal vagotomy and antrectomy

I. A. DONOVAN, C [illegible] [illegible]INE [illegible]NS, B. [illegible] [illegible]NEN, D. W. GRIFFIN,
L. K. HARDING [illegible] ALE[illegible]ER-W[illegible] *

SUMMARY

In a prospective study of proximal gastric vagotomy and truncal vagotomy and antrectomy measurements were made, before and after operation, of acid output, gastrin output and gastric emptying of a solid and a liquid meat extract meal. No relationships were demonstrable between acid output and gastrin output. Truncal vagotomy and antrectomy (TVA) produced rapid early emptying of both meals combined with gross prolongation of the overall emptying of the solid meal. Truncal vagotomy and antrectomy reduced the integrated gastrin output after either meal. Proximal gastric vagotomy (PGV) produced rapid early emptying of the liquid meal with no alteration in the early emptying of the solid meal; however, overall solid meal emptying was delayed. Proximal gastric vagotomy increased basal, peak and integrated gastrin output. In preoperative patients slow solid meal emptying was associated with higher gastrin output but after PGV the reverse was found, the slowest emptiers having the lowest gastrin output. These findings do not support the contention that a pyloroplasty should be added to PGV to reduce the hypergastrinaemia produced by the operation.

HOLLE (1974) has stated that proximal gastric vagotomy (PGV) requires the addition of a pyloroplasty in order to rectify the delay produced in the gastric emptying of solid food. The rationale is that higher than normal gastrin levels seen after PGV as opposed to after PGV and pyloroplasty (Jaffe et al., 1974) are due to delayed antral emptying and may stimulate acid output and predispose to recurrent ulceration. To assess the validity of this hypothesis we have measured the relevant physiological indices in a prospective trial of PGV and truncal vagotomy and antrectomy (TVA) in the treatment of duodenal ulceration.

Patients and methods

Twenty-one male patients with radiologically proved duodenal ulceration were randomly allocated for either PGV or TVA with a gastroduodenal anastomosis. Before and 3 months after operation the following studies were performed:

1. Basal acid output (BAO) and the peak acid output to pentagastrin 0·6 μg/kg PAO_{pg}.
2. The gastric emptying of a liquid meal of 400 ml of meat extract solution (40 g meat extract), and of a mixed meal of 400 ml of minced meat, peas, potato and milk. Measurements were made with an external scanning technique using a gamma camera and the meals were labelled with indium 113^m chelated with DTPA. The details of the method have been described elsewhere (Donovan, 1976).
3. Serum gastrin concentrations were measured by the radioimmunoassay method (Jackson et al., 1972) using an antibody which detects G34, G17 and G13. Measurements were made in the fasting state and during the gastric emptying studies at 10, 20, 30, 40, 60 and 90 min after the start of the meal. The integrated gastrin output (IGO) was devised by calculating the area under the curve.

The statistical test used to compare data was the non-parametric Mann–Whitney U test. Where correlations have been attempted, the non-parametric Spearman's ranked correlation has been applied.

Results

The results of the acid output studies are shown in *Table I*. There was no significant difference in the reduction of basal acid output after TVA compared with PGV. However, after TVA the reduction in peak acid output was significantly greater than that seen after PGV ($U = 2·6$, $P<0·01$). After PGV, 6 of the 10 patients still had a PAO_{pg} greater than 20 mmol/h.

The results of the gastrin determinations before and after PGV are shown in *Table II*. Proximal gastric vagotomy significantly raised fasting gastrin ($P<0·05$), peak gastrin (liquid meal $P<0·05$, solid meal $P<0·001$) and the IGO (liquid meal $P<0·05$, solid meal $P<0·01$). The results of the gastrin determinations before and after TVA are shown in *Table III*. Truncal vagotomy and antrectomy had no significant effect on the fasting gastrin level or on the peak response to the solid meal, but the procedure significantly reduced both the peak response to the liquid meal ($P<0·05$) and the IGO (liquid meal $P<0·005$, solid meal $P<0·05$).

The peak gastrin concentration occurred significantly sooner after TVA than before operation ($U = 2·1$, $P<0·05$). After TVA 9 of the 10 peak levels were recorded at the first estimation, 10 min after the meal. There was no significant change in the timing of the peak gastrin concentration after the solid meal following TVA or in the timing of the peak after either meal following PGV.

No significant correlations were found between BAO and fasting gastrin concentration before or after surgery. No significant correlations were found between PAO_{pg} and the IGO of the solid and liquid meals before or after surgery.

The gastric emptying results have been expressed by two indices, the first index being the peak volume of meal attained in the stomach (*Fig.* 1). This is the measurement of early emptying occurring mostly during ingestion of the meal. The lower the peak volume, the greater is the extent of the early emptying. After gastric operations the measurement of early emptying is especially important as a number of authors have described a very rapid early phase of gastric emptying which differs considerably from the later overall exponential pattern (McKelvey, 1970; Cobb et al., 1971; Clarke and Alexander-Williams, 1973; Colmer et al., 1973).

The second index used to define the emptying pattern is the $t_{\frac{1}{2}}$ of the best-fit exponential regression

TVA	BAO	1·1	0·4
	PAO_{pg}	44·2	2·6

Median values are given.

Table II: SERUM GASTRIN LEVELS BEFORE AND AFTER PGV (pg/ml)

	Preop.	Postop.	*U*	*P*
Fasting	25 (13–51)	47 (20–96)	2·1	<0·05
Peak level				
Meat extract	95 (44–308)	218 (93–534)	1·9	<0·05
Solid meal	119 (51–294)	180 (90–440)	3·2	<0·001
Integrated gastrin output				
Meat extract	606 (218–1437)	1267 (601–3900)	2·2	<0·05
Solid meal	783 (375–1934)	1399 (729–2920)	2·35	<0·01

$n = 10$; values are median and range.

calculated from the stomach volumes from the peak volume onwards (*Fig.* 1). The gastric emptying results before and after PGV are shown in *Table IV.* Proximal gastric vagotomy significantly increased the early emptying of the liquid meal ($P < 0{\cdot}01$) without significantly altering the $t_{\frac{1}{2}}$. Proximal gastric vagotomy had no significant effect on the early emptying of the solid meal but significantly prolonged the $t_{\frac{1}{2}}$ ($P < 0{\cdot}01$). The results before and after TVA are shown in *Table V.* Truncal vagotomy and antrectomy produced a significant increase in the early emptying of the liquid meal with no significant alteration in the $t_{\frac{1}{2}}$. Truncal vagotomy and antrectomy also produced a significant increase in the early emptying of the solid meal with significant prolongation of the $t_{\frac{1}{2}}$. In general, the severity of abnormality produced was greater with TVA than with PGV. The gastric emptying data have been published in full previously (Donovan, 1976).

No significant correlation was found between the $t_{\frac{1}{2}}$ of the liquid meal and its IGO before operation or after PGV or TVA. A significant correlation was demonstrated, however, between the preoperative solid meal $t_{\frac{1}{2}}$ and the associated IGO (*Fig.* 2). The longer $t_{\frac{1}{2}}$s were associated with an increase in IGO ($P < 0{\cdot}05$). After TVA no significant correlation between solid meal $t_{\frac{1}{2}}$ and the IGO was demonstrated. The values after PGV are shown in *Fig.* 3, the broken line representing the upper limit of our normal range for the solid meal $t_{\frac{1}{2}}$. No significant correlation was found. The two patients showing an abnormally long $t_{\frac{1}{2}}$ had the lowest IGO in the group, the reverse of the preoperative trend. In addition, these 2 patients had the lowest PAOs in the PGV group (0 and 0·3 mmol/h respectively).

Discussion

In the preoperative patients the expected relationship between the integrated gastrin output and the rate of solid meal emptying has been demonstrated. After

$n = 11$; values are median and range.

PGV, however, the normal relationship has altered, delayed emptying being associated with the lowest gastrin outputs in the group. These findings do not support the proposal that the delay produced in the emptying of solid food is a major factor in the production of hypergastrinaemia after PGV. This conclusion is contrary to our own earlier findings using a liquid dextrose meal and a different method of measuring gastric emptying (Jaffe et al., 1974), when we proposed that the lower gastrin levels we found after PGV and pyloroplasty as opposed to PGV reflected the increased rate of emptying produced by the pyloroplasty.

We feel, therefore, that there is no support from our present study for the contention that pyloroplasty should be added to PGV and, as others (Thompson et al., 1976) have stated, the addition of pyloroplasty negates most of the advantages of PGV.

In our present study we found that after PGV there was a slow rise and decline in gastrin levels after stimulation by the meat extract meal despite rapid early gastric emptying and a normal $t_{\frac{1}{2}}$. Five of the 10 patients having had PGV had gastrin levels greater than 90 pg/ml at 90 min from the start of the meal compared with none of the 10 before operation. These findings could, in part, be explained by decreased gastrin metabolism in the denervated gastric fundus, as has been shown in the dog by Evans and his colleagues (1974), or by some other mechanism of prolongation of the half-life of the gastrin. However, in 2 of the 10 patients there was a late secondary rise in gastrin concentration after the meat extract meal, suggesting continued stimulation of antral gastrin release. As there has been no slowing of the rate of emptying of the liquid meal, this finding suggests failure of shut-off of gastrin release. Low acid production would be the obvious mechanism to implicate, but in the 2 patients with the late rise in gastrin levels the PAO_{pg} was 31·0 and 28·8 respectively. It may be that there is some other mechanism for stopping antral gastrin release which is mediated by the innervated gastric fundus.

After TVA the peak gastrin concentration after meat extract stimulus was reached with greater rapidity than before operation. In addition, in 9 of the 11 patients the concentrations returned to basal levels by 20 min after the stimulus. These findings suggest that after TVA there is no prolonged gastrin production as was found after PGV.

After TVA the gastrin response to a meal is presumably short half-life gastrin released from the duodenum. The great prolongation of the $t_{\frac{1}{2}}$ of the solid meals after TVA was associated with an almost 50 per cent reduction in the IGO compared with before the operation, in the presence also of a great reduction in acid inhibition. The ability of the denervated duodenum to produce gastrin upon stimulation would seem, therefore, to be very limited.

Scalp and cranial substitution with autotransplanted greater omentum using microvascular anastomosis

F. S. C. BROWNING, D. S[illegible]D, D. J. E. PRICE
AND R. C. KESTER*

SUMMARY
A case is described whereby a large defect of scalp and cranium was successfully covered using autotransplanted greater omentum, revascularized by microsurgical techniques.

THE methods of covering large surface defects in man have been revolutionized by use of a free flap of skin and subcutaneous tissue which is immediately revascularized by microsurgical anastomoses. When Goldwyn et al. (1963) first transposed such skin flaps to distant sites in the dog, a new era of surgical reconstruction was introduced. Using the operating microscope, the technique of anastomosing arteries and veins of about 1 mm in diameter was first established in the animal laboratory (Krizek et al., 1965; Strauch and Murray, 1967; Fujino et al., 1972) and then applied to the clinical situation. The first successful microvascular flap operation in man was carried out in September 1972 by Harii et al. (1974). Such microvascular operations are now commonplace in many centres specializing in reconstructive surgery.

We wish to describe a case whereby an extensive defect of the scalp and skull was covered by transferred greater omentum, which was immediately revascularized by microvascular anastomosis.

Case report

The patient, a woman born in 1913, had a rodent ulcer of the right frontal scalp treated by radium needle implants in 1939. She suffered a local recurrence in April 1949 which was treated by excision and skin grafting. The graft failed in the central area and therefore, in October 1949, at Leeds, the ulcerated lesion and the underlying outer table of skull were excised. The defect was covered by a scalp transposition flap. Histology of the specimen showed an inflammatory reaction with no evidence of malignancy.

A further recurrence of basal cell cancer in 1954 was treated by local excision and skin grafting. A larger recurrence was observed in 1960, but the patient refused to undergo treatment. This lesion was eventually excised in December 1963. The defect was repaired by an acromiopectoral tube pedicle which had been prepared by seven operations between August and November 1963. The patient remained clinically free of tumour until the end of 1965, when a lesion in the left supraorbital region was discovered. This recurrence was widely excised in February 1966, removing the supra-orbital ridge. The defect was repaired with an abdominal marsupial flap which had been prepared over the previous 12 weeks by eight operations.

Between 1966 and 1972 nine further scalp lesions were excised. Histological examination confirmed multi-focal basal cell cancer with complete removal on each occasion. In January 1973 a large left frontal parasagittal recurrence was excised. A preoperative carotid angiogram had shown a partial occlusion of the sagittal sinus just anterior to its mid-point. The tumour was seen to be infiltrating the underlying bone and a 9 × 7 cm flap of bone was excised. The tumour had infiltrated the dura and the sagittal sinus and two cortical drainage veins were sacrificed to enable most of it to be removed. A complete excision would have necessitated clipping a third large drainage vein on the dominant hemisphere and ligation of the sagittal sinus and its mid-point with risk of consequent bifrontal infarction. The excised dura was replaced with cadaver dural graft. The scalp and cranial defect was covered by a further abdominal marsupial flap which had been prepared over 3 months by six operations. The patient declined postoperative radiotherapy. During the succeeding 3 years, multiple small recurrences in the scalp skin flaps were excised, including one deeper lesion.

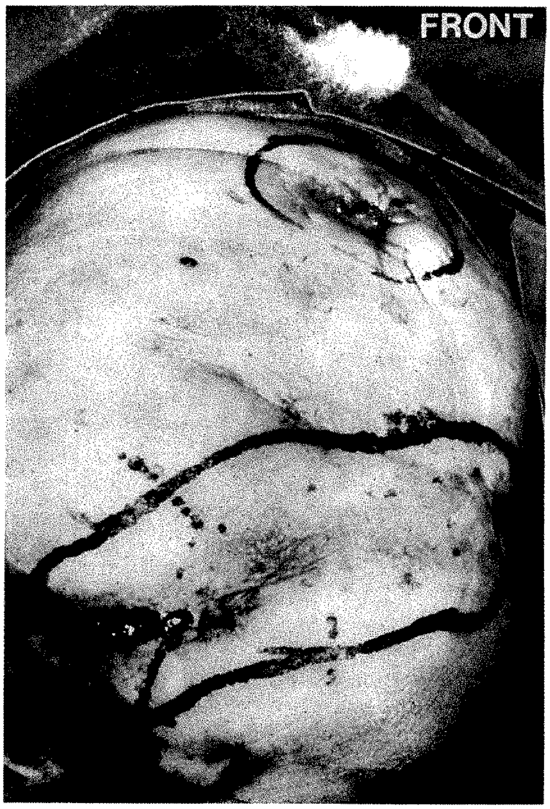

Fig. 1. Recurrences of basal cell cancer within the anterior and posterior aspects of the scalp are encircled.

In September 1976 the patient presented with two large recurrences in the scalp overlying the anterior and posterior limits of the previous craniectomy (*Fig.* 1). An electroencephalogram showed abnormal slow wave activity over the left frontal area and a computerized axial tomograph confirmed suspicions of a further extension of the parasagittal tumour in lateral and inferior directions. It was decided that extensive excision of the recurrence was indicated and that the large scalp and cranial defect would be best substituted by a free omental graft which would be revascularized by microsurgical techniques.

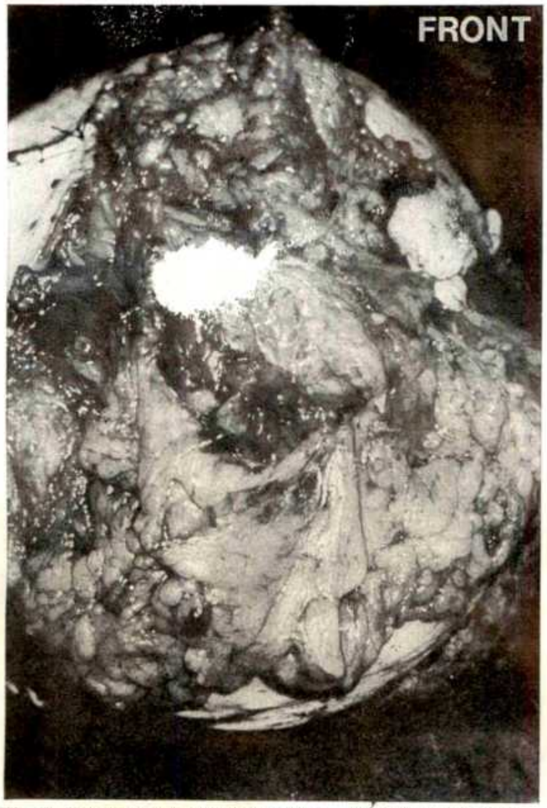

Fig. 2. Vascularized omental graft covering the scalp and cranial defect.

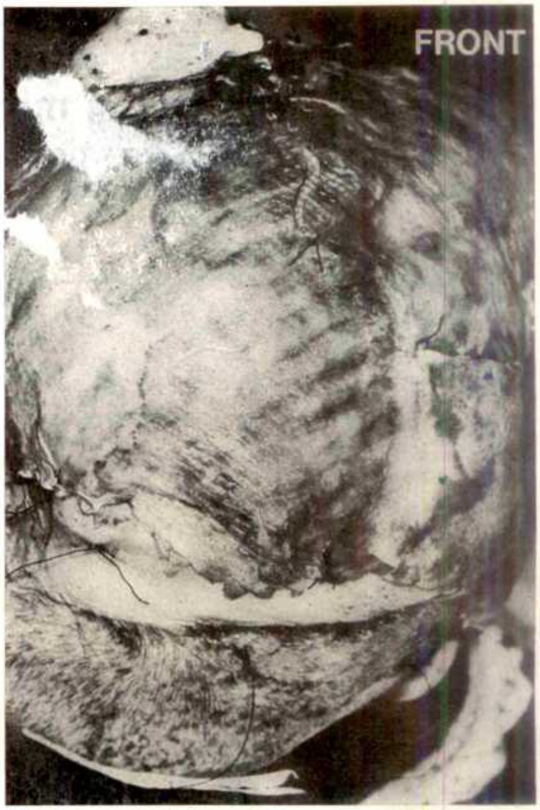

Fig. 3. Viable split skin grafts covering the omentum 2 weeks postoperatively.

Omental transfer operation (30 March 1977)

Excision of the skin and further underlying skull containing macroscopic recurrences of basal cell cancer was performed, leaving a skin defect of 17 × 12 cm and a bone defect of 12 × 9 cm. The anterior recurrence was fully excised along that part of the involved sagittal sinus and falx. The large posterior recurrence extended along the falx on both sides to a depth of 4 cm and was 3 cm in diameter, displacing but not invading the cerebral cortex. This lesion could again not be completely removed without the risk of venous infarction. All the infiltrated dura was excised and the defects were repaired with bovine dural grafts (Ethicon Ltd). The right superficial temporal artery and vein were dissected to provide recipient vessels for the free omental graft.

Through a transverse supra-umbilical incision, the greater omentum was dissected and removed from the transverse colon and the greater curvature of the stomach, preserving the right gastroepiploic vessels. The diameters of the vein and artery were about 2 mm and 1 mm respectively. Anastomosis of the superficial temporal to the gastroepiploic vessels was accomplished with a Zeiss OPMI Mark VIII operating microscope which provided zoom magnification from × 10 to × 40. The vessel ends were irrigated with heparinized saline. Interrupted Ethilon 10/0 sutures (Ethicon Ltd) were used, anastomosing first the veins (with 12 sutures) and then the arteries (with 10 sutures). The omental graft was ischaemic for about 1·5 h. Following release of the microvascular clamps, revascularization of the omentum was immediate and satisfactory and it was now plicated to cover the defect (*Fig.* 2). The surface of the omentum was next covered by split skin grafts taken from the thighs. The total operating time for the three teams of surgeons was about 11 h. Postoperatively, the patient made an uneventful recovery; the skin grafts took completely (*Fig.* 3) and she was discharged 3 weeks after operation. Six months later she had a further small superficial basal cell cancer excised from the lower occipital scalp. At 15 months after omental grafting atrophy of the omental pad is barely perceptible and the skin grafts remain healthy.

Discussion

Omentum was first transposed as a free autotransplant, using microvascular anastomosis, by McLean and Buncke (1972) to cover the denuded skull following resection of the scalp for malignancy. The left gastroepiploic vessels of the graft were anastomosed to the superficial temporal vessels with the aid of the operating microscope. Several further microvascular transfers of greater omentum to the head have been reported (Harii and Ohmori, 1973; Ikuta, 1975; Sykes, 1975). Omental transplantation by microvascular anastomosis has been used to cover the brachial plexus to alleviate incapacitating neuritis (Clodius, 1974) and to reconstruct facial atrophy (Harii, 1975; O'Brien, 1977).

As the fan-shaped cribriform mass of omentum is highly conformable and easy to work with, it readily fills irregular defects. The well-vascularized rays of fat can be pleated and refolded upon themselves without jeopardizing the blood supply, to provide a thick, protective buffer. Split skin grafts laid upon the omental cushion have an excellent chance of a successful 'take'. We are not aware of any case in which a thick vascularized omental pad has been employed to substitute cranial bone in addition to scalp tissue. Such an omental transfer operation proved highly acceptable to our patient because of the convenience and reduced hospitalization time, in contrast to her previous experiences with tube pedicle and marsupial flap repairs.

Non-occlusive acute intestinal vascular failure

ULF HAGLUND AND OVE LUNDGREN*

SUMMARY

The records of 87 patients with vascular intestinal insufficiency leading to gangrene were analysed in retrospect. In 77 patients the cause of the vascular insufficiency could be determined. In 25 per cent no organic obstruction to blood flow was found in the macroscopic intestinal vessels. The patients with non-occlusive intestinal gangrene showed a tendency to be younger and to have associated cardiac infarction more frequently than those with vessel obstructions. Moreover, non-occlusive intestinal gangrene was found more frequently following a period of systemic arterial hypotension. A history of atrial fibrillation and digitalis therapy was present with equal frequency in both groups of patients.

Based on these cases and on current animal experimental data, it is suggested that the bowel gangrene seen in non-occlusive ischaemia is due to short-circuiting of oxygen at the base of the villi in the villous counter-current exchanger. This mechanism becomes much more effective in hypotension owing to reduced velocity of the villous blood flow. The possibility is emphasized that, with a coexisting atherosclerotic narrowing in the mesenteric vascular tree, cardiovascular disturbances which are themselves not enough to alter central arterial pressure, may none the less induce regional hypotension. Such regional hypotension could lead to villous destruction and initiate a vicious circle which ends in generalized gangrene of the bowel.

INTESTINAL gangrene in the presence of a patent arterial tree has been called 'non-occlusive intestinal ischaemia' and appears to be increasing in frequency over the past two decades (Jackson, 1963; Williams, 1971). The outcome is almost invariably fatal (Williams, 1971; Lancinault and Jacobson, 1976). The cause of non-occlusive intestinal ischaemia is largely unknown, but inadequate cardiac response to minor increases in functional demand, coupled with visceral atherosclerosis, is believed to be of great importance.

The present retrospective investigation was carried out to elucidate whether the previously proposed causative factors, such as age, cardiovascular disease, hypotension and digitalis medication, were distributed in a different way in patients with non-occlusive intestinal ischaemia as compared with patients with gangrene due to intestinal arterial obstruction. Based on the results of this retrospective study and on the experimental data obtained in our laboratory, a hypothesis concerning the pathogenesis of non-occlusive intestinal ischaemia is presented.

Patients and methods

The records from 87 consecutive patients with intestinal gangrene due to acute vascular insufficiency treated between 1971 and 1975 at Sahlgren's Hospital, Göteborg, were analysed. In all cases the diagnosis was confirmed at laparotomy and/or post-mortem examination. The cause of the intestinal infarction, and in most cases the diagnosis of the associated diseases, was obtained from autopsy protocols and/or from examination of resected specimens. In 10 patients (11 per cent) no such investigation was performed and hence the cause of the intestinal gangrene was unknown. *Table I* shows the cause of intestinal gangrene in the remaining 77 patients.

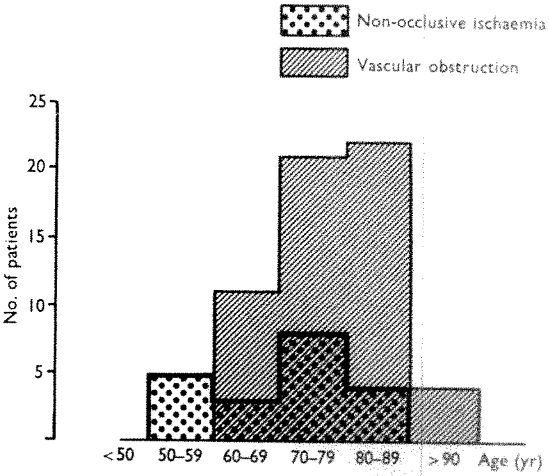

Fig. 1. The age distribution of the patients with non-occlusive intestinal ischaemia and of those with macroscopic obstruction to the intestinal blood flow.

Table I: CAUSES OF INTESTINAL GANGRENE

	No.		%	
Non-occlusive ischaemia	19		25	
Arterial embolus	34	49	44	64
Arterial thrombosis	15		19	
Venous thrombosis	6		8	
Dissecting aortic aneurysm	3		4	
Total	77		100	

In comparing the different groups the χ^2 test was used (Siegel, 1956). Thirty-four (39 per cent) of the 87 patients were men: 9 (47 per cent) of the 19 patients with non-occlusive disease were men as were 20 (41 per cent) of the 49 patients with arterial vascular occlusion (not significant).

In *Fig.* 1 the age distribution in the group with intestinal gangrene secondary to obstructive vascular disease ($n = 58$) is compared with that in the group with patent vessels ($n = 19$). The patients with non-occlusive intestinal ischaemia were on average about 10 years younger than those with vessel obstruction. Eight (42 per cent) of the non-occlusive cases were under 70 years of age compared with only 11 (19 per cent) of the patients in the group with obstruction ($P < 0{\cdot}05$).

Associated diseases

Eleven patients (58 per cent) with non-occlusive intestinal ischaemia had known grave cardiovascular diseases compared with 46 (79 per cent) of the 58 patients with vascular obstruction (n.s.) and 64 (74 per cent) of the total material (n.s.). Atrial fibrillation was found to be equally common in the different groups; thus, it was present at the time of admission in 30 (52 per cent) of the 58 patients with vascular obstruction and in 20 (59 per cent) of the 34 with superior mesenteric artery emboli. Eight (49 per cent) of the non-occlusive patients had atrial fibrillation.

Cardiac infarction was diagnosed before the onset of the abdominal symptoms in 5 (26 per cent) of the non-occlusive and in 6 (10 per cent) of the cases with intestinal vascular obstruction ($P<0{\cdot}10$). A significant period of arterial hypotension was found in 8 (42 per cent) of the non-occlusive group and in 3 (5 per cent) of the vascular obstruction group ($P<0{\cdot}05$). The cause of the arterial hypotension in the non-occlusive group was: cardiogenic (3 cases), dehydration (2 cases), postoperative hypovolaemia (1 case) and in 2 cases with significant dehydration it was not possible in retrospect to determine the exact cause. In the group with vascular obstruction the hypotension was cardiogenic in 2 cases and secondary to haemorrhage due to fractures in 1 case.

Thirteen (68 per cent) of the non-occlusive and 45 (78 per cent) of the arterial obstruction patients were on digitalis therapy at the time of the onset of the abdominal symptoms (n.s.).

Survival rate

In the non-occlusive group 2 patients (11 per cent) survived compared with 5 (9 per cent) in the occlusive group (n.s.). None of the patients where the pathogenesis remains unknown survived. Two of the 6 patients with venous thrombosis survived as did 1 of the 3 with dissecting aortic aneurysms and 2 of the 49 patients with acute arterial obstruction. The overall survival was thus 8 per cent. At the time when the clinical diagnosis was definite or sufficiently obvious to indicate laparotomy, 9 (47 per cent) of the non-occlusive group, 25 (43 per cent) of the 58 patients in the occlusive group and 42 (48 per cent) of the total had clinical signs of diffuse peritonitis and/or shock. In 24 patients (28 per cent) the disease was found to be too advanced and no active treatment except analgesics was given and 10 additional patients (11 per cent) died during the period of preoperative substitution therapy. In 7 (37 per cent) of the non-occlusive group and in 5 (9 per cent) ($P<0{\cdot}05$) of the group with vascular obstruction the diagnosis was made unexpectedly at post-mortem when, on clinical grounds, the cause of death had been thought to lie outside the abdomen.

Operative procedure

Table II illustrates the operative procedures performed, related to the diagnosis and the outcome. As already stated, only 41 of the 87 patients (47 per cent) were operated upon and, moreover, in 20 of them (23 per cent) only an exploratory laparotomy was performed. In 6 of the 7 surviving patients only a limited part of the intestine was affected and a resection of the gangrenous area was performed. In the seventh survivor the major part of the small intestine was resected and a jejunoileal anastomosis carried out.

Discussion

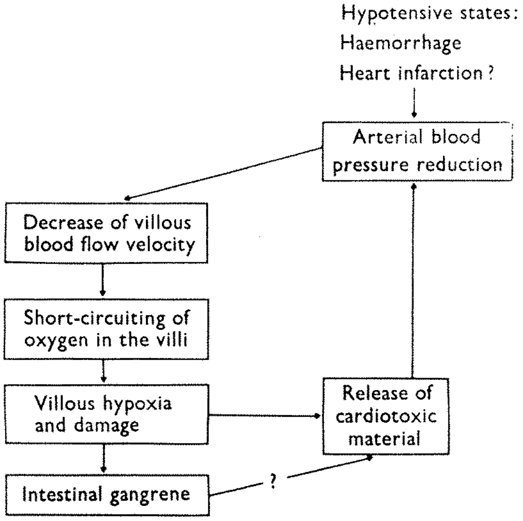
The present retrospective investigation was carried out in a group of 77 patients with intestinal infarction, in whom a thorough pathological investigation of the cause had been performed. In 19 patients (25 per cent) no obstruction to blood flow was found, as far as could be judged from inspection of the intestinal vessels. If anything, this frequency is less than would be expected from previous studies (Liavåg, 1967; Williams, 1971; Marston, 1977). Venous vascular occlusion was found in 8 per cent of patients, which is within the accepted range (Williams, 1971). The proportion of patients having intestinal infarction due to venous occlusion seems to have declined over the past 20 years (Jackson, 1963; Williams, 1971). The mortality rate in our 87 patients with intestinal gangrene was 92 per cent which is similar to that reported previously (Mavor et al., 1963; Liavåg, 1967; Williams, 1971). In the group of patients consisting of cases 'treated' conservatively or subjected only to an exploratory laparotomy ($n = 66$), the mortality was 100 per cent, as in other series (Mavor et al., 1963; Liavåg, 1967; Williams, 1971). On the other hand, 7 (33 per cent) of the 21 patients treated surgically, by resection of the devitalized part of the intestines, survived. In this, as in earlier series, the high mortality was largely due to the fact that the disease was diagnosed or suspected too late—in one-half of the cases at a time when diffuse peritonitis and/or shock was present.

Pathogenesis

Most studies of non-occlusive intestinal ischaemia have been performed on autopsy material. Although some patients may develop non-occlusive intestinal ischaemia without any obvious precipitating factor (Glotzer and Shaw, 1959; Blennerhassett and Reid, 1960; Williams, 1971), most of the reported patients have had severe cardiac failure with or without infarction (Ende, 1958; Glotzer and Shaw, 1959; Blennerhassett and Reid, 1960; Ming and Levitan, 1960; Mösslacher and Slany, 1972; Aldrete et al., 1977), or arterial hypotension and shock from other causes (Blennerhassett and Reid, 1960; Williams et al., 1967; Williams, 1971; Wiklund et al., 1976). Advanced age and digitalis medication are other important features (Williams, 1971; Renton, 1972; Lancinault and Jacobson, 1976). The current concept of pathogenesis is that increasing cardiovascular demands in these old and atherosclerotic patients leads to a failure of intestinal perfusion, due to redistribution of blood flow from the splanchnic area secondary to sympathetic activity and/or other agents causing intestinal vasoconstriction, such as digitalis (Williams, 1971; Renton, 1972; Lancinault and Jacobson, 1976). The chain of events alone, and even more so in the presence of arterial stenosis, results in ischaemia of the mucosa (Williams, 1971; Lancinault and Jacobson, 1976).

In the present study the patients with non-occlusive intestinal ischaemia were, on the whole, younger ($P<0{\cdot}05$) and had a higher incidence of myocardial infarction ($P<0{\cdot}10$) than those with blocked vessels. No significant difference was found in this study in the frequency of associated cardiovascular disease and digitalis medication between the non-occlusive patients and those with macroscopic vessel obstruction. On the other hand, non-occlusive ischaemia appeared to occur significantly more frequently secondary to a period of arterial hypotension ($P<0{\cdot}05$).

These observations are in agreement with the hypothesis that the most important factor precipitating



Hypotensive states:
Haemorrhage
Heart infarction?
Arterial blood pressure reduction
Decrease of villous blood flow velocity
Short-circuiting of oxygen in the villi
Villous hypoxia and damage
Release of cardiotoxic material
Intestinal gangrene
?

Fig. 2. The suggested 'vicious circle', illustrating the importance of intestinal mucosal lesions in hypotensive states in the development of shock.

non-occlusive ischaemia is a reduction of the intestinal perfusion pressure, however caused. It has been demonstrated in cats that a reduction of the intestinal perfusion pressure great enough to lower intestinal blood flow to 30–50 per cent of its resting value induces mucosal infarction within 2 h (Haglund et al., 1976a), and this experimental model is considered to resemble closely the clinical situation in non-occlusive intestinal ischaemia. In the experimental animal the mucosal damage first appears at the villous tip (Chiu et al., 1970; Åhrén and Haglund, 1973), which also seems to be the starting point in intestinal gangrene in humans (Williams, 1971; Marston, 1977). Although total intestinal blood flow is only moderately reduced, the hypoxic nature of the villous damage has been demonstrated (Åhrén and Haglund, 1973; Haglund et al., 1976a; Shute, 1976). Moreover, in hypotension severe enough to reduce total intestinal blood flow to 30–50 per cent in the experimental animal, the volume of blood supplying the villi is almost unchanged, although the velocity of flow in the villi is much reduced (Lundgren and Svanvik, 1973). This paradox, whereby hypoxia pronounced enough to cause tissue death within 2 h occurs in spite of an unchanged blood supply, can be explained by the extravascular short-circuiting of oxygen at the base of the villi in the villous counter-current exchanger (Lundgren, 1967; Kampp et al., 1968; Lundgren and Haglund, 1978). The villus is supplied with blood by a central arteriole and a subepithelial set of venous vessels, constructed so that the arterial and the venous blood flow in opposite directions. The distance between the two limbs of the villous vascular exchanger is less than 20 μm, which allows a significant amount of extravascular 'shunting' of oxygen in the exchanger, even during normal 'resting' conditions (Kampp et al., 1968). A four- to fivefold reduction of the villous blood flow velocity, which has been shown to occur in the cat in hypotension, without significant reduction of villous blood flow, would increase the effectiveness of the counter-current exchange mechanism considerably. In this situation the villous tips may become anoxic in spite of an unchanged blood volume supply (Åhrén and Haglund, 1973; Haglund et al., 1976a; Lundgren and Haglund, 1978). Once the mucosal damage has developed, a vicious circle is created, since the damaged intestinal tissue apparently releases toxic substances with a negative inotropic effect on the heart. This tends to intensify the hypotension, as illustrated schematically in *Fig.* 2 (Haglund and Lundgren, 1973; Haglund et al., 1976b; Lundgren et al., 1976; Haglund et al., 1978).

As mentioned above, it is generally accepted that the intestinal damage seen in non-occlusive intestinal vascular failure starts with mucosal infarction (Williams, 1971; Whitehead, 1972; Marston, 1977). The hypothesis proposed is that the mucosal damage is caused by extravascular short-circuiting of oxygen due to reduced intestinal perfusion pressure. The steps involved in, and the time course of, the development from mucosal to total bowel wall infarction are not yet known in all details. The progressive cardiovascular deterioration induced by the mucosal damage (*Fig.* 2) is certainly of importance in inducing a further reduction of the blood flow to the muscle layer. Local release of proteolytic enzymes (Haglund et al., 1977) and increased permeability to toxic substances and bacteria from the lumen and from the infarcted mucosa (Bounous et al., 1966) may also be of importance.

The pathogenic mechanism proposed above was further substantiated by the experimental finding that the same mucosal lesions developed in cats subjected to hypotension and continuous vasoconstrictor nerve stimulation as in those in which the small intestine had been denervated (Haglund and Lundgren, 1977).

A significantly high proportion of our patients with non-occlusive vascular insufficiency had an episode of hypotension before the clinical signs of gangrene developed. However, in those who did not have a recorded period of low arterial blood pressure it is quite possible that a slight and unnoticed fall in pressure, due (for example) to cardiac infarction, atrial fibrillation or dehydration, may have preceded the clinical signs. Such a small reduction of the pressure head can be enough to reduce intestinal perfusion pressure significantly, decreasing villous blood flow velocity and, thus, inducing villous damage. This possibility is supported by the frequent finding of atherosclerotic narrowing of the visceral arteries in unselected autopsy material (Derrick et al., 1959; Marston, 1977). The pressure gradients caused by such lesions can amount to 75 mmHg or more (Stoney and Wylie, 1966; Kiser and Utley, 1968). Hence, a drop in systemic blood pressure which clinically would not be named 'hypotension' may, in a patient at risk, damage the small bowel mucosa. The clinical hypotension may in turn be the result of release of cardiotoxic substances from the ischaemic mucosa (*Fig.* 2).

In the present series, resection of the involved intestine was the only treatment that saved life, regardless of the type of intestinal vascular insufficiency. However, this procedure could only be performed in a minority of the patients, mainly because of delay in diagnosis, in line with what has been found in most other reported series (Mavor et al., 1963; Williams, 1971; Marston, 1977). Other methods of treatment have, however, been described. In non-occlusive intestinal ischaemia early diagnosis by selective angiography followed by regional intra-arterial infusion of substances such as papaverine and phenoxybenzamine has been reported as successful in single cases (Boley et al., 1973; Athanasoulis et al., 1975; Lancinault and Jacobson, 1976). In arterial obstruction, surgical procedures such as embolectomy, thromboendarterectomy and bypass operations have been successfully carried out on a few patients (Marston, 1977). However, these reports are all based on a small series and 25 years after the first successful superior mesenteric artery embolectomy (Klass, 1951) the high mortality in acute intestinal vascular insufficiency has hardly fallen, if at all.

Our experimental experience on the feline small bowel suggests that treatment with intravenous administration of methylprednisolone (Haglund et al., 1976a, b) or a β_1-stimulating drug, or alternatively the intestinal instillation of an albumin solution (Haglund et al., 1976a, b), may be worth trying in patients with threatened non-occlusive intestinal vascular failure.

Changing pattern in aetiology of pancreatitis in an urban Swedish area

J.-O. SVENSSON, B. NORBÄCK, E. L. BOKEY AND Y. EDLUND*

SUMMARY

Two groups of patients admitted with a first attack of acute pancreatitis are reviewed. The first group, consisting of 105 patients, was admitted between 1968 and 1969; the second group of 204 patients was admitted between 1974 and 1975. These groups were compared with one of 454 patients admitted between 1956 and 1960 whose details were published earlier by our unit (Edlund et al., 1968). The aim of this study was to determine whether the incidence of factors associated with pancreatitis within the population of the city of Göteborg had changed in the 20-year period. In the 1956–60 group gallstone disease was the main associated factor (68 per cent), but in the later groups alcohol-induced pancreatitis assumed the leading role (68 and 66 per cent respectively). Alcohol-induced pancreatitis tended to occur at a younger age than gallstone pancreatitis. Thirty-one per cent of 449 patients admitted with an acute attack of alcoholic pancreatitis in the two last periods of study had had previous attacks.

THE association between pancreatitis and either gallstone disease or alcoholism is well documented. Up to a decade ago, gallstone disease was commonly implicated (Bockus et al., 1955; Richman, 1956; Howard and Jordan, 1960; Edlund et al., 1968). In some recent reports from Britain gallstone disease still predominates (Imrie and Blumgart, 1975; Imrie and Whyte, 1975; Read et al., 1976). Recently, however, an increased incidence of alcohol-induced pancreatitis has been reported. In 1972 Kager et al. in Stockholm reported a high incidence of alcoholism among male patients with acute pancreatitis. Similar reports have come from the USA (Olsen, 1974; Ranson et al., 1974; Ranson et al., 1976). A rise in the incidence of alcohol-related acute pancreatitis has been reported from Denmark (Lindahl and Røder, 1976; Madsen, 1976) and also from Britain, where alcoholism has so far been uncommon as a cause (Gillespie, 1973; Imrie, 1974; Trapnell and Duncan, 1975).

The aim of the present study was to determine whether the incidence of associated factors in patients admitted to Sahlgren's Hospital with an acute attack of pancreatitis had changed during three separate periods over 20 years. The patient population is that of a university teaching hospital which handles all emergency cases in the area. The relative incidence of factors may thus represent the true proportion in this region of Sweden. We wanted to know if there had been a changing pattern in the aetiology of pancreatitis in the city of Göteborg, with a population of approximately 450 000 inhabitants, during 20 years. There have been only slight changes of the population during this period.

Patients and methods

Two groups of patients were studied retrospectively. The first 155 patients were admitted between 1968 and 1969; 105 of these patients suffered a first attack and 50 had had previous attacks. The second group of 294 patients was admitted between 1974 and 1975; 204 of these were admitted with a first attack and the remaining 90 patients had suffered previous attacks.

In the first group, 18 patients with a first attack were diagnosed either at laparotomy or at autopsy and in the second group 27 patients were similarly diagnosed. In most cases the diagnosis was based upon clinical findings and supported by an increased urinary amylase activity. Those patients suffering a first attack were compared with a similar group of 454 patients who had been admitted between 1956 and 1960 (Edlund et al., 1968).

Patients were divided into three categories depending on associated factors:

1. Gallstone disease.
2. Alcohol overconsumption.
3. Neither gallstone disease nor alcohol abuse.

In the first category either gallstones or a non-functioning gallbladder had been demonstrated at oral cholecystography. In the second category approximately 50 per cent of the patients were heavy drinkers suffering social consequences of their alcoholism. Patients with postoperative pancreatitis were excluded from the study.

Most patients suffered either mild or moderate pancreatitis. Seventeen patients in the 1968–9 group and 21 patients in the 1974–5 group were considered to have severe disease. The treatment of all patients with mild or moderate pancreatitis over the 20-year period was uniformly conservative without the use of specific drugs. Laparotomy was performed on a few patients where the diagnosis was doubtful. Six patients with severe pancreatitis in the 1974–5 group were treated with peritoneal dialysis.

Patients with a first attack

Aetiology: There was a significant difference between the aetiological factors associated with the 1956–60 group and those associated with the two later groups (*Table I*). In 1956–60 gallstone disease was a factor in 310 out of 454 patients (68 per cent), whereas alcohol-induced pancreatitis accounted for only 65 patients (14 per cent). In the 1968–9 group alcohol-induced pancreatitis assumed a leading role, accounting for 71 out of 105 patients (68 per cent) and gallstone disease accounted for only 21 patients (20 per cent). This changing trend from gallstone-induced to alcohol-induced pancreatitis is confirmed in the 1974–5 group, where 135 out of 204 patients (66 per cent) were alcoholics and only 54 patients (26 per cent) had gallstones. *Fig.* 1 illustrates this changing pattern in the aetiology of pancreatitis in intervals of 10 and 5 years.

Age and sex: In the 1956–60 group there were as many women as men, but in the later groups there was a higher male incidence: 83 per cent in the 1968–9 group and 77 per cent in the 1974–5 group (*Table II*). Alcoholic pancreatitis occurred at a younger age (*Fig.* 2); thus although 33 per cent of patients were under the age of 40 in the 1956–60 series, 49 per cent were noted in the 1974–5 group. Patients with gallstone pancreatitis, however, tended to be older in the last period of study.

In the later groups there was also a higher incidence of women with alcoholic pancreatitis. Thus, 14 women were included in this category in the last period compared with a combined total of 3 in the two earlier periods. In patients with gallstone pancreatitis the sex incidence was equal in all three groups.

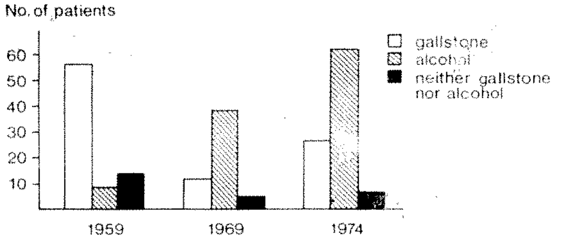

Fig. 1. Associated factors in patients with a first attack of pancreatitis in intervals of 10 and 5 years.

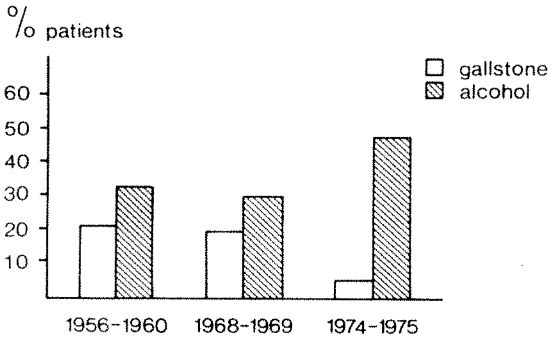

Fig. 2. Percentage of patients up to 40 years of age with a first attack of gallstone or alcoholic pancreatitis.

Mortality: The mortality in the 1974–5 group was 3 per cent as compared with 8 per cent in the 1956–60 group and 12 per cent in the 1968–9 group. Over the years there has been a reduction in the mortality rate in patients with alcohol-induced pancreatitis (*Table III*). Although 11 per cent died in the 1956–60 group only 1 per cent died in the 1974–5 group. Eleven of 14 patients with alcoholic pancreatitis who died were under 50; none of the other 3 was over 70; but most of the patients who died with gallstone pancreatitis were elderly (23 of 34 patients were over the age of 70). In the 1974–5 group 3 out of 4 patients were over 80.

Patients with previous attacks

It is common for patients with alcohol-induced pancreatitis to relapse (*Table IV*). A total of 332 patients with alcohol-induced pancreatitis were admitted in the last two groups. Of these 38 per cent (126) had had previous attacks requiring admission. Patients with recurrent alcoholic pancreatitis require a shorter mean hospitalization time than those with a first attack (89 per cent *v.* 65 per cent, less than 1 week). There was no mortality among those with recurrences.

Table I: ASSOCIATED FACTORS

	Gallstone (%)	Alcohol (%)	Neither (%)

Total	105	50	204	90

Discussion

The diagnosis of acute pancreatitis is difficult to establish clinically and there must be possibilities for error in our series. An alcoholic gastritis with elevated amylase activity may mimic an acute pancreatitis leading to overdiagnosis. A raised serum or urine amylase activity may occur in patients with biliary colic with a transient calculous obstruction of the common duct. This may result in an overdiagnosis of pancreatitis in patients with gallstone disease (Millbourn, 1941; Strömbeck, 1947; Sanchez-Ubeda et al., 1956; Bernhard et al., 1959; Adams et al., 1968).

In the male population over 15 years of age in Göteborg we have found an incidence of alcoholic pancreatitis of approximately 0·40 per thousand in 1975 as compared to 0·08 per thousand in 1960. It is also noted that increasingly younger men are becoming affected. There has also been an increase among females.

The use of alcohol in Sweden is now common among young people and those addicted have increased their consumption. The increase of patients with alcoholic pancreatitis observed in our study may be a result of this. A similar observation has been reported from Stockholm (Kager et al., 1972), where alcohol was found to play a dominant role in acute pancreatitis.

We have found the mortality rate following a first attack of alcohol-induced pancreatitis to be significant and younger people tend to be affected. The mortality is negligible, however, during a relapse. These findings are similar to those of Ranson et al. (1974) and Trapnell and Duncan (1975).

The incidence of gallstone-induced pancreatitis has decreased. Although stricter diagnostic criteria may have contributed to this decrease, we believe that the decrease is real. A possible explanation for this may be the widespread modern practice of early cholecystectomy, providing a prophylaxis against pancreatitis. However, older patients with gallstone disease are often not operated upon because of intercurrent disease. This may be the reason for the greater age of the group of patients suffering from gallstone pancreatitis. It may also provide an explanation for the relatively high mortality among this group compared with the patients with alcoholic pancreatitis.

The role of grey scale ultrasonography in the investigation of jaundice

A. J. McKAY, J. G. DUNCAN, P. LAM, D. R. HUNT AND L. H. BLUMGART*

SUMMARY

Sixty-seven patients were prospectively studied using grey scale ultrasound (GSU) to assess its possible role as part of a jaundice investigation programme. All scans were performed by one radiologist, without clinical information. When intrahepatic ductal dilatation was found an attempt was made to establish the level and cause of obstruction. The calibre of the intrahepatic bile ducts was correctly reported in 66 patients (98 per cent). Forty-three proved to have extrahepatic cholestasis, 24 had intrahepatic cholestasis. No patient with intrahepatic cholestasis had dilated ducts seen on ultrasound.

In 43 patients with obstructive jaundice, GSU accurately detected the level of obstruction in 28. This accuracy varied with the cause of obstruction. A direct indication of diagnosis was possible in 45 of the 67 patients.

In a unit specializing in the management of complicated hepatobiliary problems, GSU has been shown to be accurate in differentiating extra- from intrahepatic jaundice. Being non-invasive, it appears ideally suited for use as a screening procedure, permitting selection of appropriate invasive investigations to provide complete preoperative imaging of the biliary tree. In patients with jaundice due to gallstones, GSU may be the only imaging technique required before surgery provided good operative cholangiography is available.

THE investigative techniques of percutaneous transhepatic cholangiography (PTC), endoscopic retrograde cholangiopancreatography (ERCP) and liver biopsy are now available to aid clinicians in differentiating extra- from intrahepatic causes of jaundice. The justification for using procedures such as PTC and ERCP is that they can provide an accurate preoperative anatomical delineation of the obstructing lesion; if there is no ductal dilatation or obstruction shown, unnecessary 'diagnostic' laparotomy is avoided. Although the morbidity associated with the use of these techniques is low in expert hands, it would be preferable if they could be selected for use in specific groups of patients by a reliable non-invasive screening procedure. Indeed, in his review of cholangiography in the jaundiced patient, Elias (1976) suggested that ultrasound might permit selection of the most appropriate of the standard techniques—PTC, ERCP or liver biopsy—in the individual patient.

The initial success reported in using ultrasound scanning to differentiate extra- from intrahepatic jaundice (Taylor and Carpenter, 1974a) has been supported by subsequent more detailed studies (Neiman and Mintzer, 1977; Taylor and Rosenfield, 1977; Vicary et al., 1977). The purpose of the present study was to assess the role of ultrasound scanning as part of a jaundice-investigation programme. Our specific aims were to establish the reliability of GSU in (*a*) detecting the presence or absence of intrahepatic biliary duct dilatation; (*b*) demonstrating the level of obstruction; and (*c*) demonstrating the cause of obstruction.

Patients and methods

Sixty-seven patients were studied prospectively in Glasgow Royal Infirmary during a 15-month period ending in December 1977. The patients studied fall into two groups. Group 1, a consecutive series of 45 patients with jaundice referred to one surgical unit. In these patients the jaundice was thought to be extrahepatic or had developed following surgery performed elsewhere. Group 2, 22 patients who were initially investigated by physicians in Glasgow Royal Infirmary or elsewhere having presented with a history and clinical findings suggestive of intrahepatic cholestasis. In each case they were seen in consultation since, on the basis of clinical presentation and relevant biochemistry, an obstructive lesion could not be positively excluded.

The patients were not fasted or prepared in any specific way before the scanning. All the investigations were performed by a single consultant radiologist (J. G. D.) who was unaware of the clinical diagnosis, and was asked to determine the presence or absence of dilated intrahepatic bile ducts. In patients with dilated ducts he went on to try to establish the level and cause of the obstruction. All the patients were scanned using a Nuclear Enterprises Diasonograph NE 4200 and had a preliminary plain film of the abdomen taken with a marker placed over the umbilicus so that the presence and site of bowel gas could be identified.

Patients were examined in the supine position. Before commencing the scanning procedure the patients were taught to distend the abdomen, particularly the lower abdomen, during inspiration. Scans were performed following this manoeuvre with respiration suspended. Routine longitudinal scans were performed starting in the midline and subsequently at 0·5-cm intervals to approximately 6 cm to the right to include the head and body of the pancreas, liver hilum and gallbladder area. A 2·5-mHz transducer was used, routinely angled as steeply as possible under the costal margin, and a single sweep scan was performed. The common hepatic and bile ducts were identified most readily by performing a longitudinal radial scan with the transducer angled medially 20–35° to the vertical and also angled 5–10° lateral to the longitudinal plane (*Fig.* 1). Scans were then performed at 0·25–0·5-cm intervals to identify the extrahepatic bile ducts and neck and body of the gallbladder (*Fig.* 2). Transverse or oblique scans were performed as required.

Intrahepatic bile ducts are not normally identified on liver scanning. Dilated intrahepatic ducts are seen as short segments of fine linear or curvilinear tubules particularly in the right lobe of liver. The segments seldom measure more than 8 mm in length on the two-fifths scale and have a clearly identifiable lumen of 0·05 mm or more in diameter. In some instances, they may appear as isolated structures, e.g. when associated with local obstruction due to a hepatic mass or masses. The normal common hepatic duct may be seen lying adjacent to the portal vein on the radial scan as fine parallel lines. The normal common bile duct may be identified at a lower level, sometimes within the head of the pancreas. The commonest cause of failure to obtain a satisfactory scan was gas and faecal matter in the bowel obscuring the lower liver margin and the presence of gas in the first and second parts of the duodenum may obscure the cystic and common bile duct areas.

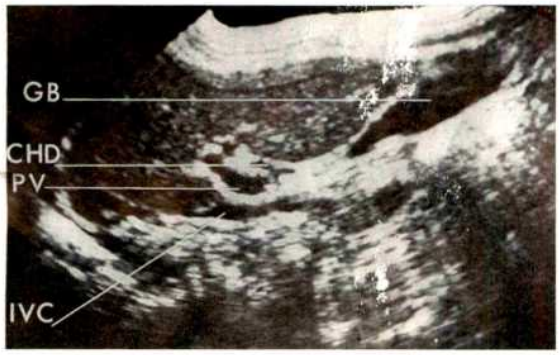

Fig. 1. Longitudinal scan of 56-year-old patient showing: GB, gallbladder containing no gallstones; CHD, common hepatic duct; PV, portal vein; and IVC, inferior vena cava.

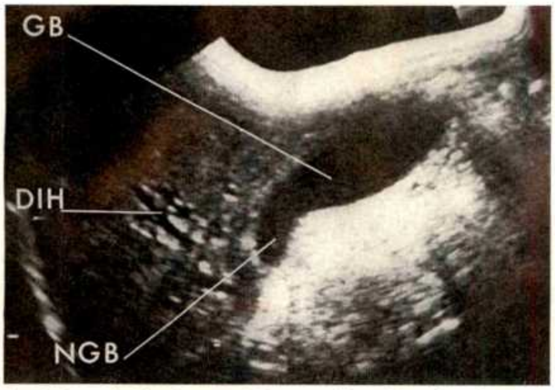

Fig. 2. Longitudinal scan of 64-year-old patient showing: GB, dilated gallbladder containing no gall stones; DIH, dilated intrahepatic ducts; and NGB, neck of gallbladder.

In each patient the ultrasound findings were confirmed by subsequent percutaneous endoscopic or operative cholangiography.

Results

Intrahepatic duct dilatation

In 67 jaundiced patients, dilated intrahepatic ducts were reported in 42 patients and non-dilated in 24 (*Table I*). In only 1 patient was the calibre of the ducts not identified, and this was because the liver could not be adequately visualized on scanning. There were no false positive results for dilatation in either group and no false negative results in group 2. The overall accuracy of GSU in predicting the presence or absence of dilated intrahepatic ducts was thus 98 per cent.

Level of obstruction

Forty-three of the 67 patients proved to have extrahepatic cholestasis (*Table II*). Ultrasound scanning indicated the level of obstruction in 28 of these 43 patients. The accuracy of prediction varied depending on the cause of obstruction. In only 11 of the 20 patients with gallstone disease was the level detected (*Table II*). However, in 7 of the 10 patients with malignant obstruction the level of obstruction was identified, and in all but one patient in the post-cholecystectomy group, the level of obstruction was seen at the time of scanning. The remaining 7 patients had different causes for their jaundice, including liver metastases, carcinoma of the gallbladder and chronic pancreatitis, and in 5 of the 7, the level of obstruction was correctly indicated by ultrasonic cholangiography.

Table I: INTRAHEPATIC DUCT DILATATION

Ultrasound findings		Cholangiography/ operative findings
Dilated ducts	42	42
Non-dilated ducts	24	24
Ducts not identified	1	Dilated

Overall accuracy 98 per cent.

Table II: LEVEL OF OBSTRUCTION

Diagnosis	No. of patients	Level indicated by ultrasound
Gallstones	20	11
Pancreatic carcinoma	10	7
Post-cholecystectomy	6	5
Miscellaneous	7	5

Table III: GALLSTONES (24 PATIENTS)

Ultrasound findings		Cholangiography/ operative findings
Dilated ducts	20	20
Non-dilated ducts	4	4
Gallstones in gallbladder	22	24
Gallstones in gallbladder and common bile duct	2	13

Filling defects	2	Liver metastases	2

Cause of jaundice

Gallstone disease: In 22 of the 24 patients with gallstone disease, gallstones were identified by ultrasound. In the remaining 2 patients the calibre of the intrahepatic bile ducts was correctly reported, but the gallbladder was obscured by intestinal gas and no comment could be made on the presence of gallstones (*Table III*).

At the time of subsequent operation, 11 patients were found to have gallstones only in the gallbladder and in all but one case these had been reported by the ultrasonographer. Of these 11 patients, 9 had dilated intrahepatic bile ducts and 4 also had a dilated common bile duct seen at the time of ultrasound scanning.

Thirteen patients had stones both in [illegible]adder and the common bile duct at the time [illegible]sequent surgery. In 12 of the 13, gallstones were identified in the gallbladder by ultrasound but in only 2 patients were common bile duct stones specifically reported.

Among the 24 patients with gallstones, 4 had an additional pathological diagnosis as a potential cause of jaundice. Two patients had gallstones with no bile duct dilatation and subsequent liver biopsy showed them to have chronic active hepatitis and primary biliary cirrhosis respectively. One patient with known alcoholic cirrhosis developed jaundice and was shown by ultrasound to have a gallstone in the left hepatic duct causing intrahepatic duct dilatation. The fourth patient had dilated ducts and gallstones detected by ultrasonography; subsequent duodenoscopy performed for gastrointestinal haemorrhage revealed an ampullary carcinoma not detected by ultrasound.

Carcinoma of the head of the pancreas: In 10 patients the cause of jaundice was malignant obstruction at the lower end of the common bile duct. Eight patients had a carcinoma of the head of the pancreas or of the periampullary region and 2 patients had ampullary carcinoma. In one patient no view of the intrahepatic ducts was obtained by ultrasound and this patient was subsequently shown to have a carcinoma of the head of the pancreas (*Table I*). Of the remaining 7 patients with a carcinoma of the head of the pancreas, a pancreatic mass was detected by the ultrasonographer in 5 cases, a mass was suspected in a further case and the pancreas could not be identified on scanning in the last patient. No periampullary abnormality was reported by ultrasound in the 2 patients with ampullary carcinoma.

Post-cholecystectomy damage to the common bile duct: Six patients were referred after iatrogenic damage to the common bile duct following surgery performed elsewhere. In 5 of the 6 patients in this group the level of obstruction was identified by the ultrasonographer (*Table II*) and in none of these cases was any extrinsic mass or other cause for the obstruction identified by scanning. The diagnosis of iatrogenic bile duct damage was thus made by exclusion. In the remaining patient, intrahepatic bile duct dilatation was noted but the common bile duct was not identified and so the cause of obstruction could not be indicated.

Miscellaneous: The remaining 27 patients had a variety of causes for their jaundice (*Table IV*). The presence or absence of intrahepatic ductal dilatation was correctly indicated by ultrasound in all 27 patients and the additional detail available indicated the final diagnosis in many cases.

Discussion

The results of this study confirm that GSU scanning is a reliable, non-invasive means of differentiating between intra- and extrahepatic causes of jaundice. It can therefore be used to select the appropriate invasive investigation for each patient, and we would advocate its use at an early stage in the investigation of the jaundiced patient. A high degree of accuracy in separating intra- from extrahepatic causes of jaundice is possible by history taking, clinical examination and liver function tests. Although the level of alkaline phosphatase, particularly taken in relation to the level of the serum transaminases, is probably the best of the commonly used liver function tests in differentiating extrahepatic obstruction from hepatocellular disease there is a non-specific pattern in up to 40 per cent of patients (Stern et al., 1973) and this has been our experience. While our results show ultrasound to be highly reliable in detecting the calibre of the intrahepatic bile ducts, it is of advantage to the surgeon to know both the level and cause of obstruction, and it is important to establish how accurately ultrasound can provide this detailed information.

In our hands the ability of ultrasound to indicate the level of obstruction is dependent to a large degree on the cause of obstruction. Twenty-four of our patients had gallstone disease, of whom 13 had gallstones in the common bile duct at the time of surgery; in only 2 patients were these specifically detected by ultrasound. These results are similar to the experience of other workers, and in their recent report on 150 jaundiced patients, Taylor and Rosenfield were able to identify only 3 of 21 common bile duct stones (Taylor and Rosenfield, 1977). In a similar study reported by Vallon et al. (1978), 5 of 14 common bile duct stones were detected. These results are somewhat disappointing since gallstone disease is the commonest cause of jaundice in patients referred to the surgeon. In most patients with gallstones ultrasound will give the cause of the jaundice, but will often be unable to establish the exact level of obstruction. Difficulty in defining gallstones in the common bile duct is largely due to the fact that no fluid–calculus interface is readily identifiable. Although the stone may produce an echo pattern, it cannot be separately identified from surrounding soft tissue structures.

Patients with gallstone disease present two further problems. First, ultrasound scanning may show gallstones in the gallbladder plus common bile duct dilatation, suggesting gallstone obstruction at the lower end of the duct. By the time of surgery, however, the duct may be shown to be of normal calibre and contain no gallstones. This situation arose in 4 of our patients, and since the dilatation extended below the cystic duct one must postulate that a gallstone has caused obstruction and then passed through the papilla before surgery. Certainly there is strong evidence that stones passed in this way are a frequent cause of acute pancreatitis (McCutcheon, 1968). Secondly, gallstones may be present yet not be responsible for the jaundice; 4 of our patients had such a 'double pathology'. Three of the 4 patients came to surgery on the basis of their clinical presentation, but in the remaining patient the gallstones were thought to be an incidental finding in a patient with chronic active hepatitis and she has not undergone operation.

In patients with pancreatic or ampullary carcinoma, the obstructing lesion usually causes distension of the gallbladder, and one would therefore anticipate that ultrasound would be more successful in detecting the level of obstruction. This proved to be the case in our own series, with the level being indicated by the ultrasonographer in 7 of the 9 patients in whom an adequate scan was obtained. Experience on the ability of ultrasound to detect a pancreatic mass in such patients has been extremely variable. Vicary et al. (1977) reported visualization of a mass in only 25 per cent of cases, this success being similar to that achieved by Taylor and his colleagues (1974b). However, these results are in contrast to a recently reported study by Lees et al. (1978) in which they were able to identify pancreatic carcinoma in 100 per cent of patients examined by GSU. In patients with carcinoma of the head of the pancreas, we were able to identify a definite mass in 70 per cent.

If ultrasound is to be used as a screening procedure to differentiate extrahepatic cholestasis, then it must also be reliable in detecting a normal, non-dilated biliary tree. In all our patients reported by ultrasonic cholangiography to have non-dilated bile ducts, this was confirmed by subsequent investigation. It is important to note that when each of these patients was seen before ultrasonography an obstructive lesion could not be excluded. In previous years a number of these patients might well have come to unnecessary diagnostic laparotomy.

As previously reported, it has been our aim to achieve an early and accurate diagnosis in all jaundiced patients (Blumgart, 1978), and the purpose of this study was to determine the place ultrasound should have in our jaundice investigation programme. Several recent reports have attempted to evaluate the roles of the various investigative techniques, and the exact place of ultrasound, PTC and ERCP will vary from unit to unit, depending both on the type of patient being investigated and on the availability and reliability of the techniques in any one centre. GSU is not available in all hospitals and its successful use is very much dependent on the skill and experience of the operator. All our patients were scanned by a single consultant radiologist who has not only devised an individual technique for outlining the biliary tract, but has also been routinely scanning patients with gallstone disease and acute pancreatitis for several years (McKay et al., 1977; McKay et al., 1978). It is of interest that some erroneous reports have arisen in our own hospital, when the scanning was performed by a less experienced person.

While it could be argued that the reliability of PTC in detecting dilated intrahepatic bile ducts justifies its use in all jaundiced patients, our results suggest that when gallstones and dilated ducts are identified by ultrasonography, one could justifiably proceed straight to surgery. One must be certain that the gallstones are the sole cause of obstruction, and we would recommend that where there is any doubt on clinical or radiological grounds simple duodenoscopy should precede surgery. Gallstones in the common bile duct—which in our hands cannot be positively identified by ultrasound—should be detected by operative cholangiography provided a high quality service is available in theatre.

In patients shown to have non-dilated ducts and gallstones, further investigation is required; if the clinical findings and ultrasound appearance of the liver suggest hepatocellular jaundice then liver biopsy is indicated. Some of these patients will have a history suggesting biliary obstruction, or in others intrahepatic cholestasis will be excluded by liver biopsy; ERCP will then be required.

Patients shown to have dilated ducts but no gallstones should have PTC performed to define accurately the level and cause of obstruction. In this group of patients ERCP may also be required. The particular value of ERCP is threefold: to exclude periampullary carcinoma, to demonstrate the anatomy of the lower end of a common bile duct not outlined by PTC and to permit collection of bile or pancreatic juice for cytology to distinguish the mass of chronic pancreatitis from that of pancreatic carcinoma and the benign bile duct stricture from carcinoma.

Recently when ultrasound has shown dilatation of the entire biliary tree with no gallstones and evident obstruction in the head of the pancreas, we have confined further investigation to duodenoscopic collection of fluid for cytology. With positive cytology for carcinoma we have then proceeded directly to surgery.

On the basis of our experience in the investigation of post-cholecystectomy problems, ultrasound and PTC have been used initially, but we often then proceed to ERCP, since at least 1 in every 3 patients presenting with jaundice after cholecystectomy has some abnormality in the duodenum as a contributory factor (Blumgart et al., 1977; Hunt and Blumgart, 1979).

The ultrasonic demonstr i portacaval shunts

L. A. BERGER, G. SAGOR AND PH ORGE*

SUMMARY

This study explores the use of ultrasound in th ment of patients with portacaval anast patients were studied; in 8 of these the anastomosis was well demonstrated. It is hat ultrasound should be the initial investigation to determine the patency of a shunt.

SINCE 1945 when portal–systemic shunting became a routine procedure in the management of bleeding varices over 100 000 shunts have been constructed (Bengmark, 1975). The most widely used anastomosis is the end-to-side portacaval shunt. This has the lowest incidence of occlusion because the stoma is large and all the portal blood flows through it (Dawson, 1977).

However, thrombosis can occur. In a patient who has a portacaval shunt and is bleeding from the upper gastrointestinal tract, knowledge of the patency, or otherwise, of the shunt would help management. Of the many tests available to determine shunt patency, the most reliable all involve invasive radiological procedures (Castell and Conn, 1972).

This study was conducted to see if ultrasound might offer a simple, accurate, non-invasive screening test of portacaval shunt patency.

Patients and methods

Ten consecutive patients with an end-to-side portacaval shunt were scanned. Eight patients had had their shunt constructed in the past while 2 were scanned in the first 2 postoperative weeks. One patient was known to have shunt dysfunction and had re-bled on many occasions following surgery; in the others the shunts were presumed patent on clinical grounds.

Using a Diasonograph 4102B with grey-scale attachment a series of longitudinal scans was performed in order to define the inferior vena cava and the portal vein. If the shunt was seen its surface position was marked with a grease pencil. If not, the line of the inferior vena cava and the portal vein was marked. Transverse scans were then performed at the level of the shunt or at the conjunction of the line of the inferior vena cava and of the portal vein.

When bowel gas prevented adequate visualization of the veins, the patient was turned into the left lateral decubitus position and scanned in both longitudinal and transverse planes.

Results

The portacaval shunt was shown in longitudinal section in only 2 patients. In one of these the inferior vena cava doubled in size at the site of the shunt, a reflection of high portal blood flow (*Fig.* 1). Surprisingly, in the other patient there was no change in calibre of the inferior vena cava, yet this patient had the largest anastomosis on ultrasound examination. In these 2 patients and in 3 others the shunt was well seen in transverse section (*Fig.* 2). In 1 patient the splenic vein, portal vein and inferior vena cava could be seen as a continuous arc.

Gas precluded adequate examination in 5 patients; however, after the patients had been turned into the left lateral decubitus position, the shunt was well seen in transverse section in 3.

The shape of the shunt generally resembled a dumbbell and adjacent to the stoma well-defined high level echoes were usually seen, probably due to fibrous tissue. In patients without portacaval shunts the portal vein can also be seen just anterior to the inferior vena cava, but in every case the two veins are separate and their walls can be seen to be intact.

In the patient presumed to have had shunt dysfunction, a stenotic connection between the inferior vena cava and the portal vein was clearly shown (*Fig.* 3).

Thus, in 8 out of 10 patients the status of the anastomosis was well demonstrated.

Discussion

After an end-to-side portacaval anastomosis some 12 per cent of patients will, at some time, bleed from the upper gastrointestinal tract (Reynolds et al., 1966; Foster et al., 1971; Jackson et al., 1971; Zeegan et al., 1973; Resnick et al., 1974; Bengmark, 1975). Forty per cent of these haemorrhages will be due to varices. This accords well with the 5 per cent incidence of thrombosis of end-to-side portacaval shunts (Voorhees et al., 1970; Foster et al., 1971; Jackson et al., 1971; Resnick et al., 1974).

Demonstrating that varices are present is not sufficient to conclude that they are the source of bleeding. Following a successful shunt varices will persist in 40–70 per cent of patients gradually reducing in size over several years (Ellis et al., 1956; Reynolds et al., 1966; Jackson et al., 1971). Bleeding from varices can occur with a patent shunt (Resnick et al., 1974), but this is uncommon. The demonstration of shunt patency would therefore suggest an alternative site for bleeding.

The effect of an end-to-side anastomosis on ascites is variable. Some patients become free of ascites, others more easily controlled and still others show little or no improvement (Rousselot et al., 1963). Nevertheless, the sudden deterioration of a previously stable situation can be due to shunt thrombosis.

We believe that scanning in the left lateral decubitus position will improve the rate of demonstration of portacaval shunts. In this position both the portal and systemic veins dilate and are more easily seen; colonic gas rises into the ascending colon away from the field of interest and the liver descends, thus becoming an ultrasonic window.

The 2 patients examined in the immediate postoperative period found scanning near their wound painful. Excessive bowel gas requiring the use of the lateral decubitus position added to their discomfort. How useful ultrasound examination will prove to be in a patient bleeding soon after operation has yet to be shown. Real-time scanners, which are less unpleasant for an ill patient, or scanning from the side, away from the wound, may be better alternatives. It is in the immediate postoperative period, when shunt thrombosis accounts for 20–25 per cent of deaths

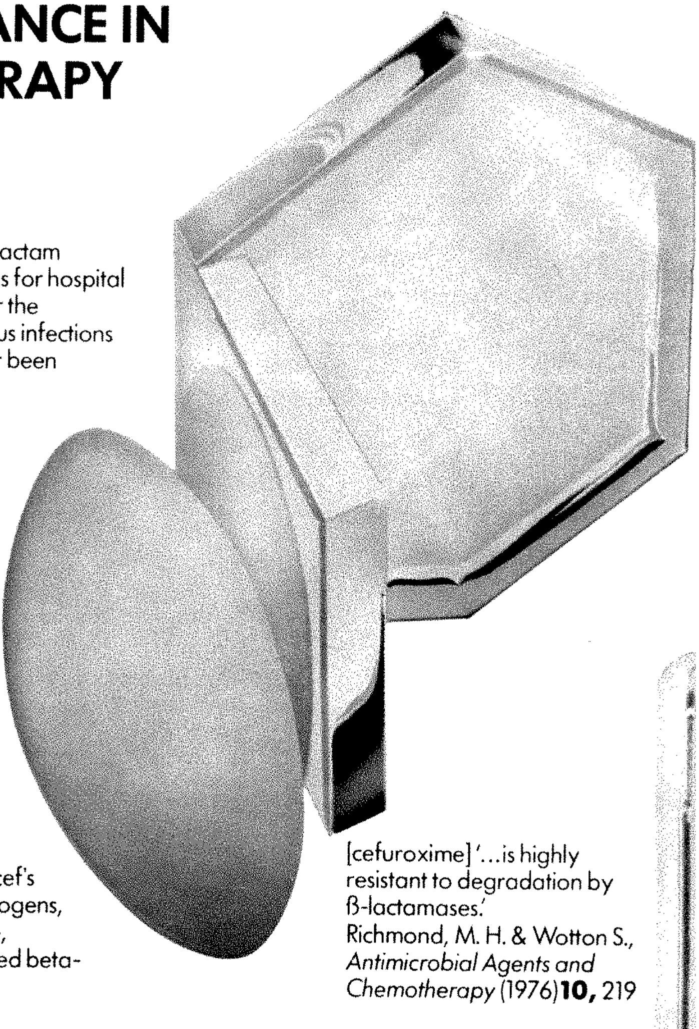
ZINACEF

cefuroxime sodium

A MAJOR ADVANCE IN ANTIBIOTIC THERAPY



Zinacef is a new, broad spectrum, beta-lactam antibiotic offering important advantages for hospital practice. It is particularly appropriate for the treatment of serious, or potentially serious infections where the causative organisms have not been identified or may be mixed.

Greatly enhanced stability to beta-lactamases

The value of commonly used beta-lactam antibiotics is being constantly eroded by the growth of resistant populations of bacteria.
Zinacef has a unique chemical structure with in-built protection against beta-lactamases which effectively places it in a new class of antibiotics.

A broader spectrum than most antibiotics

The ability to resist destruction results in a greatly extended clinical spectrum. Zinacef's bactericidal effect extends to many pathogens, both Gram-positive and Gram-negative, resistant or partially resistant to established beta-lactam antibiotics.

[cefuroxime] '...is highly resistant to degradation by β-lactamases.'
Richmond, M. H. & Wotton S., *Antimicrobial Agents and Chemotherapy* (1976) **10,** 219

With important therapeutic properties

- Zinacef has high bactericidal activity.
- Adequate serum [illegible] achieved and are well maintained.
- Zinacef is widely distributed with adequate levels in sputum, bile, bone and cerebrospinal fluid.
- Zinacef is not metabolised, but excreted, active and unchanged, in the urine.
- Zinacef has minimal toxicity, giving a wide margin of safety.
- Clinical trials have shown excellent renal tolerance.
- Zinacef can safely be used in neonates.
- Patient tolerance is excellent both intramuscularly and intravenously.
- Zinacef is compatible with commonly-used intravenous infusion fluids.
- There are no known clinically relevant adverse drug interactions.
- Zinacef can be used with other antibiotics to increase the antibacterial cover.

> '...this wide antibacterial cover should make it [Zinacef] a useful antibiotic for the treatment of infections requiring prompt parenteral therapy before the causative pathogen has been identified.'

ZINACEF

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 gram and infusion pack of 1·5 gram. All containing cefuroxime as cefuroxime sodium.

Indications
Serious bacterial infection, especially where the organisms have not yet been identified.

Conditions include:
Chest infections
Septicaemia
Soft tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Urinary tract infections
Ear, nose and throat infections
Meningitis
Gonorrhoea

Dosage
Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 gram t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary.
Infants and children: 30 to 100mg/kg/day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in two or three divided doses.
Gonorrhoea: Single dose of 1·5 gram (2 x 750mg i.m. into different sites).

Contra-indications
Hypersensitivity to cephalosporins.

Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria.
Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine.
As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.

Cephalosporins at high dosage should be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.

Side effects
Adverse reactions are rare and generally mild and transient, e.g., rashes, gastro-intestinal disturbance, candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).

Storage
The powder in the infusion pack and vials should be stored below 25°C and protected from light.

SHOCK

Trasylol®

aprotinin

increases the chances of survival in traumatic-haemorrhagic shock

The results of a large German field study[1]: Marked reduction of mortality when Trasylol was applied early. Precise clinical investigations in 70 shock patients by an Australian double-blind study[2]) provided an explanation and further proof for the effectiveness of Trasylol in shock: With Trasylol development of post-traumatic respiratory insufficiency (shocklung) was less frequent.

*Registered Trade mark of Bayer Germany

Bayer BAYER

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short-term infusion (5 ml/min to the patient in the recumbent position); thereafter every 4 hours 200,000 KIU slowly i.v.

Precautions
Trasylol may in very rare cases (less than 0.1%) cause hypersensitivity reactions.

Presentation
Ampoules of 100,000 KIU (Kallikrein Inactivator Units)
Ampoules of 200,000 KIU*

(Hellstrom and Jackson, 1970; Foster et al., 1971), that ultrasound could play its most important role.

Conclusion

This report and a previous smaller series (Goldberg and Patel, 1977) have shown that ultrasound can demonstrate end-to-side portacaval anastomoses clearly in most patients. We, therefore, suggest that it should be the initial investigation for shunt patency. Angiography would then be reserved for those patients in whom ultrasound had failed to demonstrate the shunt or for confirmation that a shunt had thrombosed.

Addendum

Since we submitted this paper the patient with the stenotic shunt has undergone a successful mesocaval shunt. Two further patients have had their portacaval shunts clearly demonstrated: one was widely patent and the other markedly stenotic. The latter patient was bleeding from varices.

Grey-scale ultrasonography and endoscopic pancreatography after pancreatic trauma

A. G. VALLON, W. R. LEES AND P. B. COTTON*

SUMMARY

We have recently used grey-scale ultrasonography and endoscopic pancreatography to investigate 11 patients with symptoms attributed to pancreatic trauma weeks, months or even years earlier. The pancreas was normal in one patient, and another, who presented with pain and jaundice after a car accident, was shown to have cancer of the pancreatic head. The remaining patients all had local lesions due to trauma; ultrasound showed a mass or cyst close to the point of duct obstruction or stenosis shown on pancreatography. Ultrasonography and pancreatography can together provide a precise map with which to plan effective management in patients having suffered pancreatic trauma.

THE pancreas is vulnerable to an external crushing injury such as may occur in a road traffic accident. Severe pain usually develops within hours and frequently leads to emergency laparotomy, at which damage to other organs may well be apparent. Specialist imaging investigations have little place in this context. However, we have recently seen 11 patients some time after the initial accident in whom persisting symptoms have been attributed to the injury. Grey-scale ultrasonography and endoscopic pancreatography have provided valuable information in the management of these patients.

Patients and methods

There were 8 men and 3 women, with an age range of 13–58 years (*Table I*). All except 3 patients were investigated within 6 months of injury and had been unwell throughout that period. Two patients had been having intermittent symptoms for 6 and 15 years following injury. Five patients had been involved in road traffic accidents; 4 others had been injured during sporting activities, in all 4 the injury had seemed trivial at the time and 2 players had been able to complete the game in which they had been playing. One patient had been assaulted and another claimed to have developed pancreatic-type pain after having been blown across a street by a bomb in Vietnam. Eight of the patients had undergone at least one surgical procedure before our investigations (*Table I*).

Grey-scale ultrasonography was performed using a modified Nuclear Enterprises Diasonograph NE 4102 with NE 4104 grey-scale facility. Gastroduodenoscopy and cholangiopancreatography were performed in the standard manner under mild sedation (Cotton, 1977).

Results

Ultrasonography was performed in 9 patients (*Table I*). No useful information was obtained in *Case* 3 who was examined shortly after surgery. In *Case* 10 a normal pancreas was correctly demonstrated. The other 7 scans showed pancreatic abnormalities which were localized in 6; 2 of these mass lesions were reported as cystic (*Table I*) (*Fig.* 1). Ultrasonography suggested multiple abdominal abscesses in *Case* 7; she required further urgent laparotomy and drainage of the abscesses. A pancreatic transection was demonstrated and a left hemipancreatectomy proved curative.

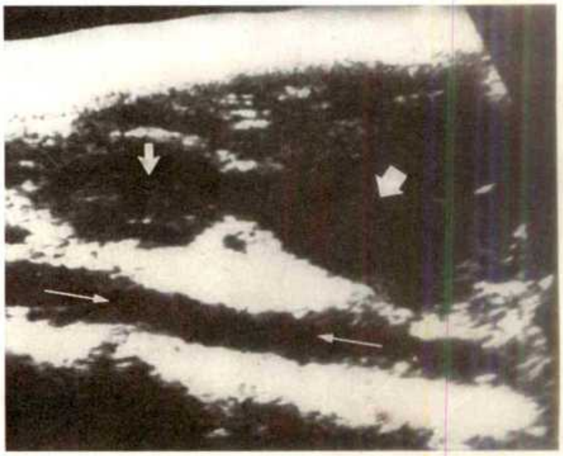

Fig. 1. (*Case* 4.) Longitudinal ultrasound scan showing the aorta posteriorly (long arrows), a section through the pancreatic body (small arrow on left) and a pseudocyst extending from the pancreas into the lesser sac (large arrow on right).

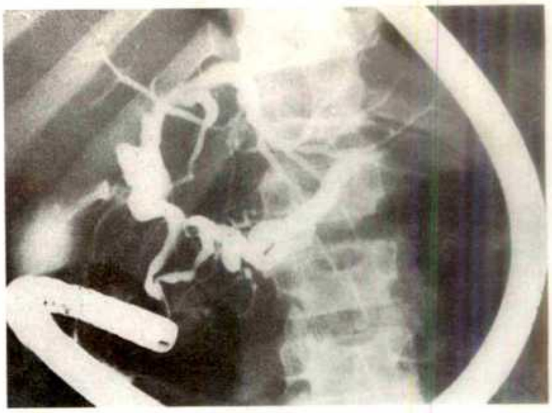

Fig. 2. (*Case* 8.) Mass lesion in the pancreatic head with upstream dilatation of the biliary system and pancreatic duct.

Endoscopic pancreatography was normal in one patient (*Case* 10), as was the ultrasound scan; it eventually became abundantly clear that this patient suffered from Munchausen's syndrome. A major duct lesion was shown in the other 9 patients (*Table I*). In *Case* 9, who had developed pain 3 days after a road traffic accident and who eventually became jaundiced, ERCP showed a stricture of the lower bile duct diagnostic of carcinoma; the history of trauma had been irrelevant. In *Case* 8, a boy of 12, ERCP showed narrowing of the common bile duct and the pancreatic duct within the head of the pancreas, and

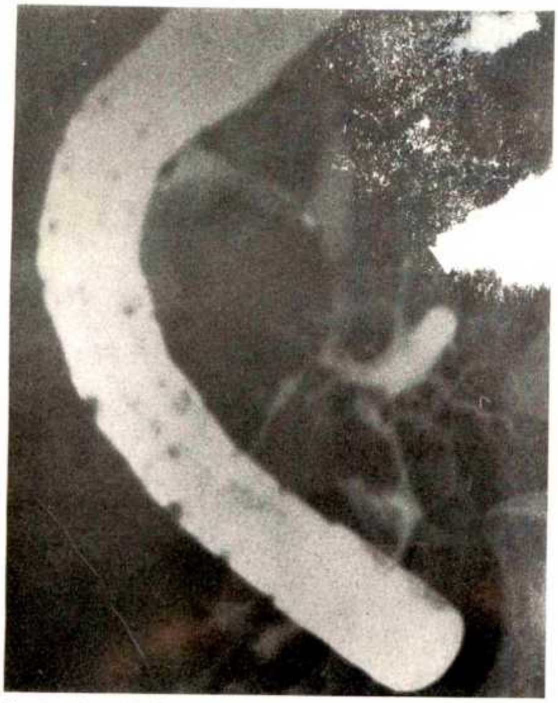

Fig. 3. (*Case* 1.) Complete pancreatic duct obstruction (arrowed) close to the papilla.

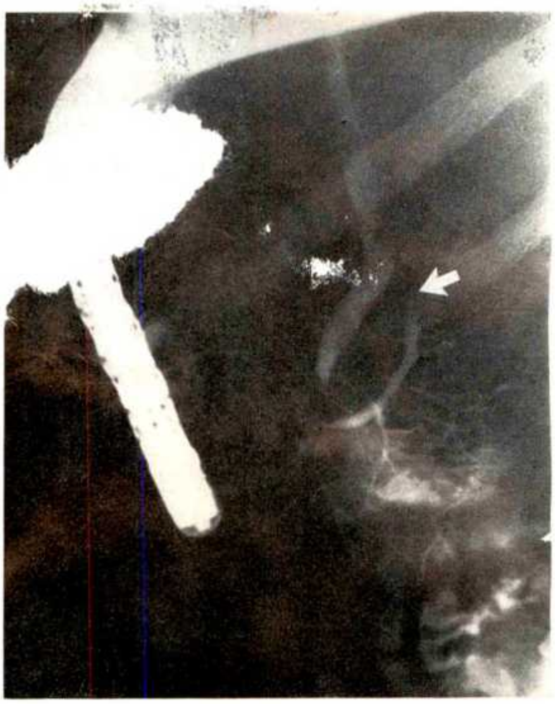

Fig. 5. (*Case* 4.) Complete obstruction of the main duct (arrowed) near the neck of the pancreas.

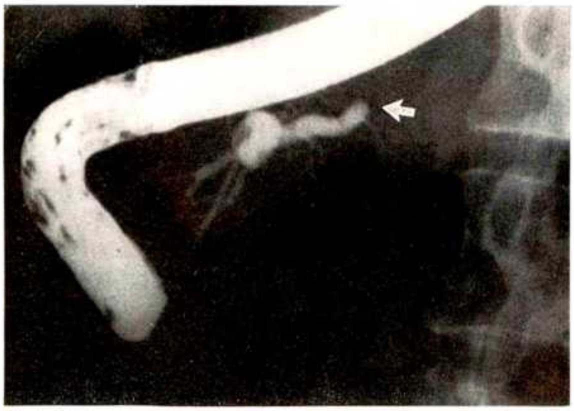

Fig. 4. (*Case* 2.) Complete obstruction in the neck of the gland (arrowed).

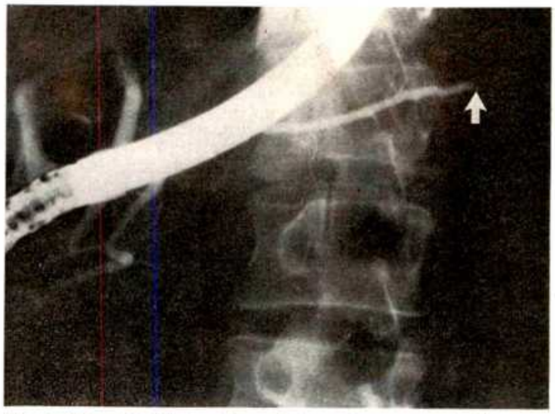

Fig. 6. (*Case* 6.) Obstruction of the main pancreatic duct close to the tail (arrowed).

upstream dilatation (*Fig.* 2). The appearances suggested a mass lesion in the head of the pancreas, which was found at surgery to be a pseudo-aneurysm resulting from erosion of the pancreaticoduodenal artery, presumably within an inflammatory mass. This patient did well after pancreaticoduodenectomy. The remaining 6 patients submitted to ERCP were all shown to have an obstruction of the main duct; the position varied considerably (*Figs.* 3–6). These abnormalities were all confirmed at surgery; in one patient (*Case* 3) the extent of the injury and adhesions from previous surgery made definitive resection impossible. One patient (*Case* 4) simply underwent pseudocyst gastrostomy with considerable short term improvement. The remaining patients have had excellent results from left hemipancreatectomy (*Table I*).

In the 8 patients who underwent both ultrasonography and ERCP, results agreed and complemented each other. The mass seen on scanning corresponded to the site of the main duct abnormality in 4 out of 5 patients.

The final patient (*Case* 5) had additional interest. He first presented with acute pancreatitis 96 h after sustaining an injury on the rugby field. Symptoms recurred following pseudocyst gastrostomy; complete pancreatic transection was recognized at a second operation and left hemipancreatectomy was performed. Despite this he continued to have repeated

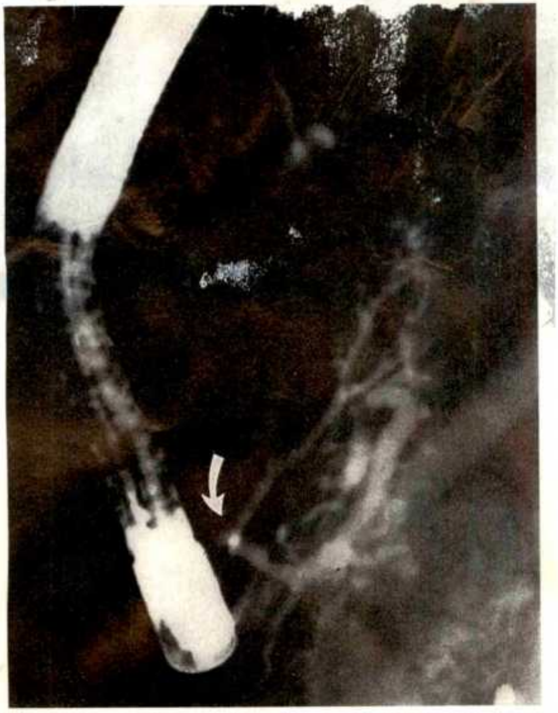

Fig. 7. (*Case* 5.) Cannulation of the accessory papilla (arrowed) and injection of contrast through Santorini's duct outlining the head of the pancreas up to the point of previous surgical resection. The ducts are abnormal, indicating chronic pancreatitis.

attacks of pancreatitis over the next 6 years. At ERCP cannulation of the main papilla revealed only the biliary system; however, cannulation of the accessory papilla and Santorini's duct outlined an abnormal head of pancreas to the point of surgical resection (*Fig*. 7). He has been pain-free following subtotal (95 per cent) pancreatectomy, but has both endocrine and exocrine insufficiency. In this patient the congenital duct anomaly (separate ventral and dorsal elements to the pancreas) probably contributed to the development and persistence of pancreatitis after the original injury.

In no case was the result of ultrasound or pancreatography misleading.

Discussion

Trauma to the pancreas is relatively uncommon, and few clinicians have wide experience in its treatment. The high initial mortality of around 20 per cent (Editorial, 1975) is rarely due to damage to the pancreas itself but to associated injuries or haemorrhage from adjacent major vessels. Steele et al. (1973) reported their experience with 85 cases of pancreatic trauma. Surgical management consisted of drainage alone for laceration and contusion that did not involve major ductal structures and segmental pancreatectomy for those that did. However, most authors state that assessment of the pancreas at operation may be difficult, and significant pancreatic injuries, including complete transections, have been missed at laparotomy (Northrup and Simmons, 1972), as in 6 of our patients. In all our patients with pseudocysts,

Table I: CLINICAL DATA AND RESULTS OF INVESTIGATIONS IN 11 PATIENTS WITH A HISTORY OF PANCREATIC TRAUMA

US, Ultrasound; ERP, pancreatography.

the ductal system was in fact disrupted and ERCP showed complete obstruction. Symptoms [illegible] slow to develop after isolated blunt pancreatic [illegible] (Blandy et al., 1959; Bracey, 1961). *Case* 5 in [illegible] series did not develop abdominal symptoms [illegible] 96 h after an injury which resulted in complete pancreatic transection. Symptoms may even be [illegible] until a pseudocyst develops weeks or [illegible] (Northrup and Simmons, 1972).

Specialist imaging investigations are unlikely to give useful clinical information in the emergency situation, although developments in ultrasound scanning may change the position. It is in patients in whom the initial injury has been insufficient to lead to early laparotomy, or where symptoms have persisted following it, that definitive investigation is important. We have found the combination of grey-scale ultrasonography and endoscopic pancreatography to provide complementary and accurate information about the pancreas (Lees et al., 1979). Pancreatography provides the essential map for any surgery which may be necessary (Cotton, 1977). Although the classic duct injury lies over the vertebral column, it is clear from this small series that the duct may become occluded at any point. Grey-scale ultrasonography should always be performed first, and this technique is particularly accurate in the diagnosis of cystic collections (Leopold, 1972; Bradley and Clements, 1974). ERCP carries a risk of introducing infection into pseudocysts; when ultrasound shows a cyst, pancreatography should be performed only as an immediate preoperative procedure.

In discussing the management of pancreatic trauma, Northrup and Simmons (1972) stress the importance [illegible] understanding the nature of the injury for formu- [illegible] surgical intervention. Preoperative [illegible] pancreatography [illegible] that this [illegible]

For total parenteral nutrition, Travenol makes SYNTHAMIN, amino acid injections, in three concentrations with and without a balanced electrolyte profile. A further concentration is available with an energy substrate.

To complement this range of solutions, Travenol provides specialized "V" and "W" administration sets, and both central and peripheral venous catheters.

Travenol also supplies the means for compounding TPN regimens in the pharmacy, using VIAFLEX plastic containers for non-air-dependent administration.

All Travenol products are supported by comprehensive technical back-up and an extensive in-service organization.

Synthamin amino acid injections

Presentation
Synthamin injections are sterile, non-pyrogenic solutions of essential and non-essential L-amino acids, provided with or without electrolytes. Synthamin 7S also provides carbohydrate as Sorbitol.

Indications
Parenteral nutrition.

Dosage and Administration
Dosage depends on patient's metabolic requirement and clinical response. For intravenous administration an associated source of non-protein energy should be administered of not less than 0.75MJ (180Kcal) per gram of nitrogen administered.

Contraindications
Severe liver disease. Solutions with electrolytes are contraindicated in renal failure.

Precautions
As with all hypertonic solutions, vein irritation may occur.

Availability
Synthamin 7S (PL0116/0043)
500ml £4.20 1000ml £7.56
Synthamin 9 (PL0116/0054)
500ml £5.15
Synthamin 9 (PL0116/0067)
500ml £4.80 without electrolytes.
Synthamin 14 (PL0116/0055)
500ml £7.35
Synthamin 14 (PL0116/0068)
500ml £7.00 without electrolytes.
Synthamin 17 (PL0116/0056)
500ml £8.90
Synthamin 17 (PL0116/0069)
500ml £8.55 without electrolytes.

Full prescribing information is available from Marketing Services Department.

Infusion cholecystography in the diagnosis of acute cholecystitis

D. J. PINTO, M. BURKE, R. A. WILKINS AND A. E. KARK*

SUMMARY

The use of infusion cholecystography as an aid in the diagnosis of acute cholecystitis was investigated in 21 patients. Seventeen of 18 patients (94 per cent) with positive cholecyst-tomograms who underwent laparotomy had confirmation of acutely inflamed gallbladders both macroscopically and histologically. These findings suggest that infusion cholecystography can make a significant contribution in reducing the incidence of misdiagnosis in acute cholecystitis, and that the investigation should be part of the management of patients in whom early surgery is planned.

THE timing of operative treatment for acute cholecystitis continues to be a controversial topic. In the past, the overwhelming opinion in Britain has favoured a policy of initial conservative management followed by planned surgery in later months. Recently, the role of early surgery has been critically re-examined as operation within the first few days of hospital admission has several advantages. Provided that the operation is undertaken by an experienced surgeon, after adequate fluid replacement and cardiorespiratory and renal assessment, the morbidity and mortality are similar to those of the conservative management of acute cholecystitis (van der Linden and Sunzel, 1970; Raine and Gunn, 1975) and both diagnosis and treatment are completed during a single hospital admission with a rapid return to full activity (Editorial, 1976). However, if a policy of early surgery is to be widely adopted, accurate diagnosis is mandatory and thus a critical evaluation of clinical and investigative data is desirable.

The most widely used diagnostic radiographic test in acute cholecystitis is intravenous cholangiography (Thorpe et al., 1973) but its reliability has been questioned (Eckelberg et al., 1970; Mujahed et al., 1974) and there is a mortality of 1 : 5000 (Love, 1976). Oral cholecystography is time-consuming (12–16 h), may require repetition and the contrast medium may not be absorbed from the gastrointestinal tract.

The non-invasive technique of ultrasonography is useful in delineating gallbladder size and wall thickness, and the presence of calculi. However, ultrasonography is not widely available and the results obtained are closely dependent on interpretation. In addition, the presence of gas in the alimentary tract adjacent to the gallbladder prevents ultrasonic demonstration of this organ in about 20 per cent of patients (Meire, 1978).

Because of the limitations of current methods of diagnosis of acute cholecystitis the radiographic technique described by Love (1976) merits further investigation. The technique consists of rapid visualization of the inflamed gallbladder by infusion cholecystography using Urografin. Love (1976) showed a 96 per cent correlation between a positive infusion tomogram of the gallbladder and histological evidence of acute inflammation. The method is particularly suited to an emergency situation as it requires no special preparation and only takes about 40 min to perform.

We report a pilot study where infusion cholecystography was used as a diagnostic aid in patients undergoing planned early cholecystectomy for acute cholecystitis, and where the radiological, operative and histopathological findings were compared in each case.

Patients and methods

Twenty-one consecutive patients who were admitted to one surgical firm with a clinical diagnosis of acute cholecystitis were studied. The average age was 60·3 years (range 46–76) and 52 per cent of the patients were women. All the patients presented with pain in the right hypochondrium with or without a history of nausea and vomiting. Localized peritonism was found on palpation. Leucocytosis and pyrexia were present in all cases. Nasogastric suction, intravenous fluid replacement and regular analgesia were instituted on admission.

Technique

An initial scout film of the right upper quadrant of the abdomen was taken, 300 ml of 30 per cent methylglucamine diatrizoate (Urografin) was infused intravenously over a period of 15–20 min. Anteroposterior tomographic cuts of the gallbladder area were then made, starting at a level one-third of the distance from the anterior abdominal wall to the top of the table and proceeding forward at 1 cm intervals for 4–5 cm. The tomographic cuts were immediately reviewed by the radiologist and further radiographs obtained if necessary.

Results

Eighteen of the 21 patients had a positive infusion tomogram of the gallbladder and underwent early operation. Seventeen of these tomograms clearly demonstrated a curvilinear opacity, about 3–5 mm thick, delineating the contour of the gallbladder (*Fig.* 1) and one showed diffuse opacification only in the gallbladder area. One of the positive tomograms also showed that the fundus of the gallbladder was grossly thickened (*Fig.* 2). This increased thickness was contiguous to the curvilinear opacity, suggesting an intramural lesion rather than an intraluminal opacity. The scout film did not reveal an opaque stone and a tentative radiological diagnosis of carcinoma of the gallbladder in an inflamed organ was made.

Seventeen of the 18 patients with positive infusion tomograms were found to have acutely inflamed gallbladders at laparotomy. Four had macroscopic evidence of focal necrosis especially in the fundus and of these one had a pericholecystic abscess. The eighteenth patient had a normal gallbladder but was found to have a sealed-off perforation of a duodenal ulcer in the anterosuperior aspect of the first part of the duodenum. There was considerable periduodenal oedema with adhesions between the gallbladder, duodenum and hepatic flexure of the colon. In this patient the tomogram showed diffuse opacification in

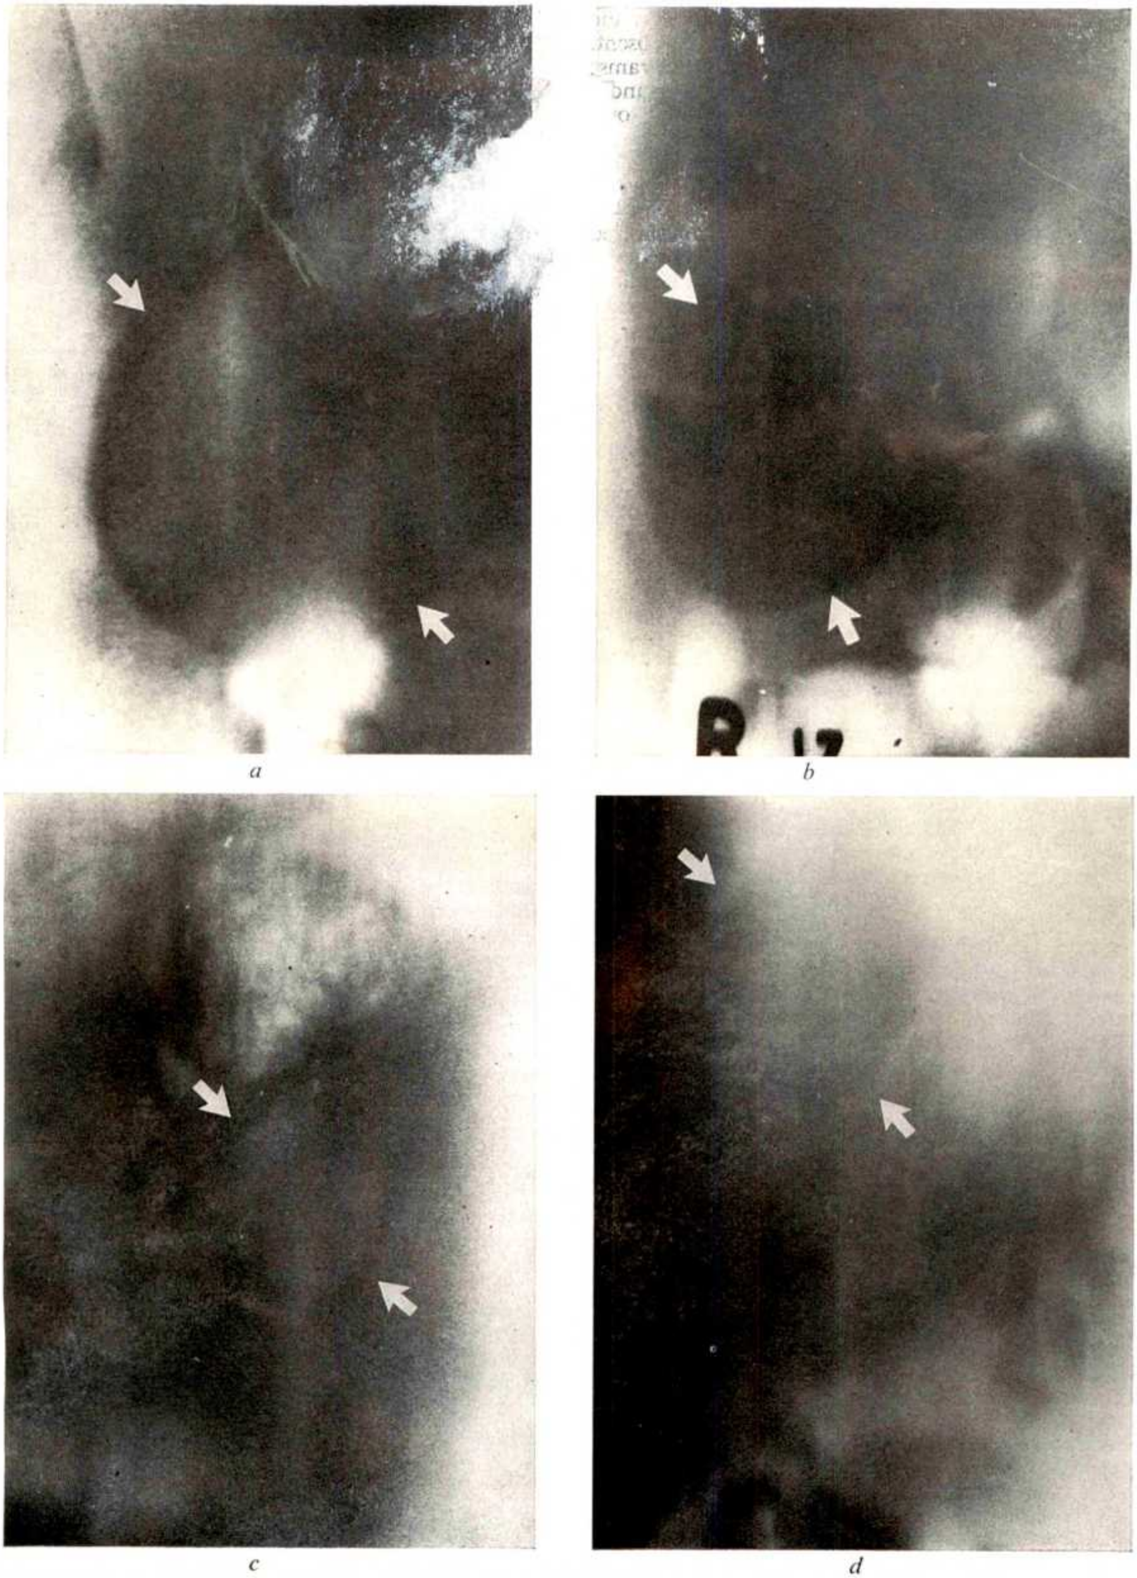

Fig. 1. White arrows demonstrate a translucent area surrounded by a curvilinear opacity a few millimetres thick, i.e. the gallbladder wall.

the gallbladder but the cur the hallmark of an inflamed gal Three patients had negative in they were treated conservatively and be weeks later were investigated by means cholecystogram and barium meal. In one, cholecystogram and barium meal were norm second had a normal cholecystogram but the ba meal showed a duodenal ulcer. The third patient h a normal barium meal but the cholecystogram showe stones in the gallbladder. However, at subsequent cholecystectomy 4 weeks after initial hospitalization, there was no macroscopic or histological evidence of recent inflammation. Thus, in 2 of the 3 patients with negative infusion tomograms there was no subsequent evidence of gallbladder pathology and, although gallstones were found in the third, there was nothing to suggest recent acute inflammation.

Histopathology of the 17 inflamed gallbladders confirmed acute inflammation with areas of total mural necrosis in some instances. Moreover, the intramural mass demonstrated on one tomogram was found at laparotomy to be a carcinoma in an inflamed gallbladder. This patient died 2 days later from a massive pulmonary embolus and autopsy confirmed the operative and radiological findings.

Discussion

The diagnosis of acute cholecystitis is often difficult to make and substantiate. Whereas acute appendicitis often poses similar problems of diagnosis, operation is usually simple and most surgeons would err on the side of caution and accept removal of some normal appendices rather than overlook acute inflammation. However, cholecystectomy is a major operation and patients with acute cholecystitis are usually middle aged or elderly; therefore , misdiagnosis at operation is seldom an acceptable risk. The incidence of faulty diagnosis varies from 6·0 per cent, reported by McCubbrey and Thieme (1959), who defend a conservative management policy, to as much as 33 per cent, reported by Holden et al. (1952). Halasz (1975) analysed 238 patients with a clinical diagnosis of acute cholecystitis and noted that in 47 patients (20 per cent) conditions other than cholecystitis were ultimately found. These included: renal problems 38 per cent (18 of 47), liver pathology 25 per cent, acute pancreatitis 21 per cent, appendicitis 11 per cent and pulmonary inflammatory disease 4 per cent. Fifty-seven of 191 patients underwent early operation and 5 (9 per cent) were found to have other pathology masquerading as acute cholecystitis. The remaining 134 had gallbladder disease confirmed radiologically at a later date. Furthermore, only two-thirds of patients with acute cholecystitis present with the typical clinical symptoms and signs (Staniland et al., 1972). With regard to management, the few controlled investigations that have been reported indicate that conservative and planned early surgical management of acute cholecystitis both carry much the same mortality and morbidity (van der Linden and Sunzel, 1970; Raine and Gunn, 1975; McArthur et al., 1975). With the likelihood of increasing recourse to early surgical management of the disease the need for a reliable objective investigation becomes paramount.

In a canine model, Moncanda et al. (1977) demonstrated by autoradiography that ^{125}I-labelled contrast material was taken up by inflammatory cells, both intravascularly and in the oedematous tissues of an inflamed gallbladder wall, while it remained confined to the vessel in a normal gallbladder. It was thought that the hyperaemia with tissue fluid equilibration of contrast material together with contrast-laden inflammatory cells was responsible for the curvilinear opacity noted when infusion tomography is performed in the presence of an inflamed gallbladder as described by Love (1976). However, Morin et al. (1977) pointed out that in 63 of 2867 patients (2·2 per cent) undergoing intravenous urography, incidental visualization of an opacity in the right hypochondrium was noted. This was thought to represent the gallbladder wall although none of these patients had symptoms of gallbladder dyspepsia or evidence of inflammation.

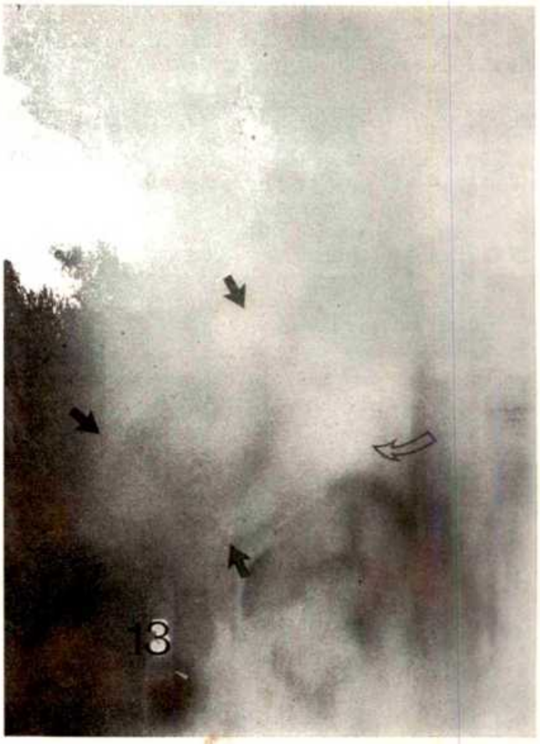

Fig. 2. Closed arrows demonstrate the curvilinear opacity and the open arrows show the intramural thickening mainly in the fundus. This was diagnosed radiologically as carcinoma in an inflamed gallbladder.

In this series of 21 patients positive infusion cholecystograms were obtained in 18 patients, the remaining 3 being negative. Of these patients one was shown to have an active peptic ulcer, one remains undiagnosed and one was shown to have gallstones at the elective operation. It may be that this patient had a mild attack of cholecystitis which rapidly subsided, but it may equally be that the symptoms were caused by some other condition as yet undiagnosed and the presence of gallstones was fortuitous.

Seventeen of the 18 patients who underwent operation after a positive infusion cholecystogram had acute inflammation of the gallbladder at laparotomy which was confirmed by histology. Review of the tomogram of the eighteenth patient showed that, although opacification was present in the region of the gallbladder, it was a diffuse opacification and not a curvilinear rim opacification as seen in acute inflammation. This was an error in interpretation rather than a false positive. Greater experience with the technique should improve interpretation and minimize the number of false positives. A clinical misdiagnosis was therefore made in 4 of the 21 patients (19 per cent). Acute renal problems masquerading as acute cholecystitis are often misdiagnosed according to Halasz (1975). The technique of infusion tomography lends itself well to the ruling out of this particular error of diagnosis as the kidney and pelvicaliceal systems are also demonstrated if a plain radiograph of the abdomen is taken after the infusion.

Operative choledochoscopy

A. KAPPAS, J. ALEXANDER-WILLIAMS, M. R. B. KEIGHLEY AND G. T. WATTS*

SUMMARY

We have reported the results of 121 examinations with the rigid choledochoscope performed by 13 different surgeons between 1969 and 1977. Pre-exploratory choledochoscopy was performed in 48 patients with a diagnostic accuracy of 94 per cent.

Post-exploratory choledochoscopy was used in 73 patients to define whether the common bile duct had been adequately cleared of stones. Fifty-one patients were correctly assessed as having a clear duct and unsuspected residual calculi were demonstrated by choledochoscopy in 13 patients. However, choledochoscopy failed to identify 9 patients with retained stones. The accuracy of post-exploratory choledochoscopy alone was 87 per cent and the accuracy of post-exploratory cholangiography was 82 per cent, but when choledochoscopy was combined with post-exploratory cholangiography there were no errors. We conclude that the addition of choledochoscopy to conventional radiological techniques is likely to reduce the incidence of residual calculi after choledochotomy.

RETAINED stones in the biliary tree after bile duct operations continue to embarrass and concern surgeons. In the literature, the reported incidence of retained stones ranges from 1·9 per cent (Nora et al., 1977) to 14 per cent (Hall et al., 1973). Although non-invasive techniques can be used for the postoperative removal of overlooked stones through the T tube track (Burhenne et al., 1974) or by endoscopic papillotomy (Classen and Demling, 1974), the aim should be to prevent stones being left behind at the time of operation.

On-table cholangiography before duct exploration and via a T tube after exploration has been shown to reduce the incidence of retained stones after biliary operations (Havard, 1970). However, both radiological techniques are subject to errors of interpretation and technical failures (Hall et al., 1973). Choledochoscopy is an alternative diagnostic technique applicable before and after duct exploration (Longland, 1973). Schein and colleagues (1963) proposed that on-table cholangiography should always be combined with choledochoscopy, but this practice has not gained widespread acceptance. Most reports of good results with choledochoscopy have been from individual surgeons with particular interest and expertise (Finnis and Rowntree, 1977). This experience does not necessarily reflect what should be the expectation of any general surgeon having to deal with biliary disease. We feel that it is important to document the results of choledochoscopy in the hands of all surgeons who perform cholecystectomy, whether they are experienced consultants or trainee registrars.

The development of fibreoptic instruments has renewed an interest in choledochoscopy, but the flexible fibreoptic choledochoscope has presented difficulties in manipulation (Shore et al., 1971), sterilization and image reproduction (Nora et al., 1977). Despite a recent report of excellent results with the flexible choledochoscope (Finnis and Rowntree, 1977), we and others have found the rigid choledochoscope to be more acceptable and easier to handle (Griffin, 1976). The rigid choledochoscope is a right-angled instrument with a lens system allowing visualization of objects from infinity to within almost direct contact with the lens. The instrument has a light-gathering element, an infusion channel and biopsy attachment. To view the duct system it is necessary to distend the bile duct with a continuous flow of saline.

Patients and methods

We have assessed the effectiveness of choledochoscopy from a study of 110 patients having 121 duct explorations during the years 1969–77. Choledochoscopy was used by a total of thirteen surgeons in all six surgical firms in our hospital. Choledochoscopy was performed before and/or after duct exploration using a rigid right-angled instrument (Storz 280 22A [Rimmer]).

The choledochoscope was inserted into the supraduodenal common bile duct through a 0·5-cm choledochotomy incision between stay sutures after mobilization of the peritoneum lateral to the second part of the duodenum. The stay sutures were crossed over one another to secure a reasonably watertight closure over the choledochoscope whilst the irrigation fluid was infused into the duct. The proximal common hepatic ducts were visualized first and the choledochoscope was reinserted for examination of the distal bile duct and ampulla, which was normally recognized by frond-like projections from the mucosa. The choledochoscope was sterilized in Cidex for 10 min between examinations and then rinsed in warm water. The eyepiece was cleaned with povidone-iodine.

Pre-exploratory choledochoscopy was used in 48 cases either instead of or as well as on-table cholangiography. Post-exploratory choledochoscopy was used in 73 cases to check that all stones had been removed or to confirm a negative conventional duct exploration. A final diagnosis of bile duct stones was based upon the following criteria: (*a*) positive findings during duct exploration; (*b*) filling defect seen on postoperative T tube cholangiography; or (*c*) demonstration of retained stones during annual clinical and biochemical follow-up.

Results

Accuracy of pre-exploratory choledochoscopy

Forty-eight choledochoscopies were performed before exploration of the duct and the procedure was used as the predominant method for diagnosing choledocholithiasis. On-table cholangiography was used in only 15 of these patients. Choledochoscopy indicated that the duct was clear in 36 cases (12 with negative on-table cholangiography) but in 3 of them stones were later demonstrated in the distal common bile duct by T tube cholangiography or repeat operation (2 of these 3 patients had negative on-table cholangiography). The presence of stones was demonstrated by choledochoscopy in 12 cases (3 with positive on-table cholangiography) and in all of them calculi were subsequently extracted from the duct. Furthermore, choledochoscopy correctly identified

the number of stones present in 10 of the 12 patients. The overall accuracy for pre-exploratory choledochoscopy was 94 per cent and there were no false positive findings (*Table I*).

Accuracy of post-exploratory choledochoscopy
Seventy-three choledochoscopies were performed after exploration of the common bile duct and in these cases post-exploratory T tube cholangiography was used in 29 patients. The endoscope findings indicated that the duct had been adequately cleared of stones in 60 cases (21 with negative post-exploratory T tube cholangiography but 3 with positive findings). In 9 of these cases, however, post-exploratory cholangiography (3 cases) or subsequent T tube cholangiography (6 cases) demonstrated residual common bile duct calculi. Of the 9 patients with false negative choledochoscopy findings, 6 had retained stones in the distal common bile duct whilst in 3 the stones were located in the intrahepatic branches. The presence of retained stones was demonstrated by choledochoscopy in 13 patients in whom the surgeon had considered the ducts to have been satisfactorily cleared after conventional duct exploration (5 of whom had had negative post-exploratory T tube cholangiography). The overall accuracy of post-exploratory choledochoscopy was 87 per cent (*Table II*). The accuracy of post-exploratory cholangiography was 83 per cent, but when choledochoscopy was combined with cholangiography there were no errors.

Complications of choledochoscopy
There was one patient with infected bile (10^5 counts/ml of *Escherichia coli*) who became hypotensive and oliguric within 24 h of operation due to septicaemia from *E. coli*. In this patient high infusion pressures were necessary in order to clear the duct of debris before choledochoscopy. There were 13 cases of wound infection (11 per cent), and one case each of mild postoperative pancreatitis, clinical cholangitis and postoperative jaundice. All were treated successfully by conservative management.

Two patients, both over the age of 80, died in hospital following operation, one from pulmonary embolism and the other from renal failure. At postmortem there was no detectable trauma to the bile ducts caused by the choledochoscope and no residual calculi were found.

es there remains a small incines following choledocholithos in common duct instrumentaholangiography (Hall et al., e probably reflects individual tensive experience. It is imestrict the performance of to very experienced surgeons, and st be placed on adjunctive procedures (Sh and Shore, 1970).

In some centres the routine use of the rigid choledochoscope has reduced the incidence of retained stones to below 2 per cent (Nora et al., 1977). In our series 13 general surgeons, including registrars under training, have performed 121 choledochoscopies; the incidence of retained stones in this series was 6·6 per cent. We noticed, however, that most of the cases with retained stones occurred in the early period of the study when the participants first started to use choledochoscopy.

The majority of patients having pre-exploratory choledochoscopy did not have a conventional ontable cholangiogram and a small supraduodenal choledochotomy was performed for choledochoscopy. If the results of endoscopy were normal, primary duct suture was performed. The experience of choledochoscopy in these patients has provided us with the opportunity to examine the accuracy of this procedure. However, the results of careful on-table cholangiography (Schulenburg, 1969), particularly when combined with contact cholangiography (Hugh and Campbell, 1976), are so good that choledochotomy should not now be necessary for diagnosing or excluding choledocholithiasis. In view of the known hazards from sepsis of opening the common bile duct, even when the duct does not contain calculi (Keighley and Graham, 1971), we do feel that pre-exploratory choledochoscopy is necessary in the presence of normal on-table cholangiography findings.

The use of choledochoscopy after choledochotomy has been shown to be effective in avoiding residual stones in 11 of our patients (19 per cent). However, in our hands there were 9 other patients in whom residual calculi were missed by post-exploratory choledochoscopy, usually when the surgeon had only little choledochoscopic experience. Fortunately, in 5 of these cases stones were demonstrated by the post-exploratory T tube cholangiogram. Because of these results most of our surgeons now adopt the policy of performing both cholangiography and choledochoscopy after duct exploration. It is disappointing but not surprising to find that our results using the rigid choledochoscope are inferior to those reported by one enthusiast using the flexible instrument (Finnis and Rowntree, 1977). The disadvantages of flexible choledochoscopy are that the instrument requires considerable endoscopic expertise, it is difficult to sterilize, easy to damage and very costly to repair. It is thus an unsatisfactory instrument for most surgical units and unlike the rigid choledochoscope cannot be recommended as standard equipment for every district general hospital.

Choledochoscopy does not appear to increase the morbidity of biliary surgery provided that the irrigation fluid is not introduced under high pressure. In this study saline was usually delivered at a pressure of between 70 and 80 mmHg. Higher pressures have [illegible] sepsis in [illegible] series — [illegible] less than the normal rate of seps[illegible] [illegible]gst patients having a choledochotomy [illegible]hout antibiotic cover (Keighley, 1977). Nevertheless, most surgeons using the choledochoscope considered that patients were at risk from endogenous wound sepsis, and prophylactic antibiotics were recorded as being given to 84 (76 per cent) of the patients either before or during the operation.

Choledochoscopy in our series has proved to be safe for the patient and easy for the theatre staff. Progressive experience in the use of the procedure should reduce the incidence of retained common bile duct stones, particularly if it is combined with post-exploratory cholangiography.

Acknowledgements

We wish to thank Mr R. M. Baddeley, Mr N. J. Dorricott and Mr G. D. Oates for allowing us to study their cases and to acknowledge the secretarial help of Miss V. A. Price.

Modified surgical procedures in intestinal tu

B. D. PUJARI*

SUMMARY

The results of modified surgical procedures in intestinal tuberculosis in 79 patients are presented. Special emphasis is laid on the role of limited ileocaecal resection and ileoplasty. These procedures are safe, quick and easy with preservation of functional portions of the bowel. They are of immense value in emergencies in chronically ill and emaciated patients.

INTESTINAL tubercular lesions are often multiple and may present either with chronic insidious onset, subacute or acute intestinal obstruction or with perforation. The treatment is complicated because of the associated widespread peritoneal involvement, massive and often caseous mesenteric lymphadenitis, multiplicity of lesions and extra-abdominal disease with its systemic effects.

Before the invention of anti-tubercular drugs these lesions were treated by short-circuiting procedures such as ileoileostomy and ileotransverse colostomy (Aird, 1957). With the availability of specific drugs, the aim of the surgical approach shifted towards local extirpation of the disease with wide ileal resections, right radical hemicolectomies and combinations of these procedures (Anand and Phatak, 1961; Abrams and Holden, 1964; Bhansali and Desai, 1968; Byrons and Mann, 1969). Recognizing the complications, side effects, limited applicability and the risks involved, simple procedures such as limited ileocaecal resections and 'strictureplasties' have evolved. Here the aim is to overcome the complications with preservation of as large a portion of functional bowel as possible. Short-circuiting procedures are used only in duodenal tuberculosis. Segmental resection of the small bowel is adopted only when multiple strictures are close together.

Patients and methods

This report consists of our experience with various surgical procedures in 79 cases of intestinal tuberculosis. This study does not include cases of gastric tuberculosis, isolated appendicular tuberculosis, colonic tubercular lesions distal to the ileocaecal region and those cases in which only biopsy was done because of miliary lesions, extensive adhesions and matting.

Ileocaecal lesions

Ileocaecal resections: Ileocaecal tubercular lesions are usually hypertrophic and involve variable portions of terminal ileum, caecum and ascending colon. Usually these lesions are associated with a group of enlarged and sometimes caseous lymph nodes in the ileocaecal angle. Occasionally the chain of lymph nodes extends to the origin of the superior mesenteric vessels, in which case there are usually multiple lymph nodes in the ileal mesentery. This was the sole lesion in 26 patients. In these patients treatment consisted of mobilization of the ileocaecal region and limited resection extending for 5 cm on either side of the lesion with end-to-end ileocolic anastomosis. The abdomen was closed after reperitonealization.

Ileal lesions

Early lesions: Very early lesions were better left alone. Only biopsy of the regional mesenteric lymph node was done to confirm the diagnosis and no complications were seen following biopsy in 6 cases.

Ileal resections: Multiple ileal short segment of bowel were treated by ex of the bowel bearing the lesions. In the early one or two isolated lesions were also treated by e end-to-end anastomosis. With increa experience plasty, however, this procedure wa only for multip lesions in a short segment of bowe

Bypass procedures: Th was used in 3 cases of duodenal tuberculosis. Gastrojejunostomy was the procedure used.

Ileoplasty: The tubercular lesions of small bowel, which were often multiple (from 2 to 19 lesions in an individual), were treated by ileoplasty. The bowel was opened longitudinally on the antimesenteric side across the lesion extending the incision on either side of the lesion. A portion was trimmed from the edge of the lesion for biopsy and the bowel was closed transversely in two layers. Even in tubular lesions, long loop ileoplasties were done. In granulomatous conditions, an oval or rhomboid portion of the lesion was excised on the antimesenteric side with its long axis in the line of the bowel and the defect was closed transversely. Even when perforation had occurred, an ileoplasty was performed, the perforation being included in the rhomboid or oval portion. In some cases this suture line was reinforced with a patch of omentum. In 32 patients, 59 ileoplasties were done, the maximum being eight ileoplasties in one individual. In every case a regional mesenteric lymph node was removed for biopsy.

Nineteen patients underwent a combination of these procedures. Six had ileocaecal resection and ileal resection, 8 had ileocaecal resection and one or more ileoplasties and 5 had ileal resection and ileoplasties.

Results

All the patients received antitubercular drugs for 6–18 months postoperatively. All patients were followed up for 6 months to 7 years. There were 2 deaths in the series. Two patients who had undergone resection developed faecal fistulas. Both patients recovered well on a conservative regimen under cover of antitubercular drugs. One patient who had undergone ileoplasty was re-explored after 6 months for obstruction due to an omental band. At that time the ileoplasties had healed.

Only a few glands in the mesentery were involved by tuberculosis. One female patient reported after 2 years for uterine leiomyoma. She had undergone resection for ileal strictures. Both the anastomotic sites had healed well and there was no trace of tuberculosis in the abdomen or pelvis (*Table 1*).

Discussion

The surgical treatment of intestinal tuberculosis has gone through many phases. Bypassing the stenosed segment either by enteroenterostomy or by ileotransverse colostomy was practised in the pre-antibiotic era (Aird, 1957). This practice has two main disadvantages; it is likely to produce a blind loop syndrome and the strictures in the remaining segments may produce fistulas or recurrent obstructions (Faulkner, 1964).

With the advent of specific antituberculous drugs, tuberculosis of the intestine was treated in a more radical fashion either by right hemicolectomy with or

without extensive removal of the lymph nodes for ileocaecal tuberculosis, or by wide resection for intestinal tuberculosis (Anand and Phatak, 1961; Abrams and Holden, 1964; Bhansali and Desai, 1968; Byrons and Mann, 1969). These procedures had the advantages of eradicating the disease locally.

These extensive and often multiple procedures may not be tolerated by a patient who is hypoprotinaemic, anaemic and toxaemic, or by a patient presenting with a perforation. Moreover, the lesions are often widely spaced and not suitable for resection without causing loss of normal bowel. Tuberculous perforations are usually associated with strictures (Bhansali and Desai, 1968). These patients may not tolerate a single resection. Simple suture of the perforation with drainage of the peritoneal cavity as advocated by Prakash (1975) has limited application.

Limited resection of the ileocaecal region for tuberculosis was advocated by Dutta Gupta in 1958 and Sharma and Mehta in 1964. It can be done through a relatively small incision and requires less mobilization of the colon, thus avoiding injuries to the ureter, kidney and duodenum. It is safe, quick and a comparatively easy procedure, suitable for use in an emergency. These merits have been specifically emphasized by Singh et al. (1973) and Joshi (1976). This limited resection can be used in all cases of ileocaecal tuberculosis irrespective of the degree of obstruction and stage of the disease. Tuberculous lesions of the small intestine with minimal obstruction should be left alone. They are unlikely to cause trouble. A segment of the intestine bearing multiple lesions is best treated by resection with end-to-end anastomosis provided the patient's condition permits.

In multiple lesions two criteria are used for selection of lesions for enteroplasty, the more important being the degree of reduction of the lumen. If the lumen is reduced by half or more enteroplasty is always selected. If the reduction of the lumen is not so great, the decision is based on the number of lesions that need enteroplasty and also the fitness of the patient. We have done eight enteroplasties in an individual. The second criterion is the degree of proximal hypertrophy of the bowel. In tubular lesions causing obstruction a long loop ileoplasty gives excellent results.

In hypertrophic granulomatous lesions the disease is more on the antimesenteric side of the bowel, with a pad of fat on the mesenteric side. In these patients an oval or rhomboid excision of the lesion on the antimesenteric side of the bowel with transverse anastomosis gives excellent results. This excision can also encircle the associated perforation.

The value of different forms of treatment for varicose veins

BJARNE HAMILTON JAKOBSEN*

SUMMARY

In a controlled clinical investigation 516 patients with previously untreated saphenous varices were divided into three treatment groups according to a stratified group comparative design. The patients in treatment group 1 underwent a radical operation under full anaesthesia; the patients in group 2 were treated by means of minor operations followed by injection/compression therapy; the patients in group 3 were treated by means of injection/compression therapy alone. The results were evaluated both objectively and subjectively 3 months and 3 years after treatment, the follow-up being 100 per cent and 98·1 per cent complete at those times. With regard to the period of disability among those patients with jobs outside the home (63·8 per cent), there was a statistically significant difference between the three groups, the median period of disability being 14·2, 7·6 and 0 days respectively. In all three treatment groups the results were worse after 3 years than after 3 months, but the difference was significantly less following radical operation than after combined treatment, and significantly less following combined treatment than after injection/compression therapy alone. The patients were randomized and treated by the author and the results of treatment were evaluated by the author and partly controlled by another investigator.

It is concluded that the primary treatment for incompetence of the saphenous veins should be a radical operation.

For more than a hundred years both operative treatment and sclerotherapy have been used for the treatment of varicose veins, and disagreement persists concerning the relative merit of and the indication for these two principal forms of treatment. Following a long period during which operative treatment clearly dominated, the international literature covering the past 15 years reveals an increasing enthusiasm for sclerotherapy as described by Fegan (1967) and Sigg (1976). In a number of publications, results apparently up to the standard of those following operative treatment have been reported (Reid and Rothnie, 1968; Chant et al., 1972; Stother et al., 1974; Doran and White, 1975), and it is maintained that outpatient sclerotherapy is not only more economical for the community but also more advantageous for the individual patient than operative treatment involving a period of stay in hospital (Piachaud and Weddell, 1972).

An attempt to evaluate and compare the different forms of treatment for varicose veins by use of the current literature is relatively fruitless. Despite many detailed classifications and definitions of varices (Borschberg, 1967), clinically the concept of varices covers a broad spectrum of venous complaints in the lower extremity, ranging from dilated venules, dilated superficial veins and varicose saphenous veins to severe post-thrombotic syndromes. It is obvious that different methods of selecting and composing the clinical material have a bearing on the results of treatment which can be obtained, and even a fair degree of certainty regarding the comparability of material is extremely rare.

The therapy employed is most frequently described in the literature as 'radical operation' or 'injection–compression therapy'. Not only do these descriptions cover individual conceptions of what the method involves, but sclerotherapy and operative treatment alike may be carried out with a greater or lesser degree of expertise, which changes the significance of the treatment.

In comparing results the period of observation after completion of treatment is important, because the number of unsatisfactory results following treatment is a function of the period of observation (van der Stricht, 1966).

In the current literature the results of treatment for varicose veins have been stated in countless ways. They may be based on an objective or subjective evaluation, each of which may be made according to numerous, differing criteria. Furthermore, despite well-defined criteria, two or more investigators may evaluate a given result differently (McAdam et al., 1976).

In an attempt to eliminate some of these difficulties, a controlled clinical investigation was started in Copenhagen in 1972 with the objective of comparing the results of three different forms of treatment for varicose veins. The treatment and the evaluation of the results have been carried out by the author according to well-defined principles and criteria.

Patients and methods

A series of 516 patients at the Copenhagen County Hospital in Glostrup who presented with saphenous varices, not previously treated, were registered with regard to sex, age, height and weight as well as the type and degree of varicosity. They were divided into three treatment groups according to a stratified group comparative design. Thirty-three patients left the study because they moved from the hospital area or because they sought treatment elsewhere during the period between the preliminary examination and the actual treatment in the hospital.

A subsequent analysis of the treatment groups showed that not only was there full comparability with regard to the chosen criteria, but also with regard to the duration of the illness, symptomatology and the other relations shown in *Tables I–V*.

Treatment

Group 1: The 161 patients in this group were admitted to hospital for about 30 h and underwent a radical operation under full anaesthesia. The operation consisted of flush ligation at the saphenofemoral and/or saphenopopliteal junction, extraction of the long and/or short saphenous vein, ligation of incompetent perforating veins located by clinical examination and avulsion of varicose tributaries by way of multiple small incisions. The mean number of incisions was 8·2 (range 2–17). The median duration of the operation was 34 min for unilateral varices and 68 min for bilateral varices.

All figures are percentages.

Table IX: DISTRIBUTION OF OBJECTIVE AND SUBJECTIVE EVALUATIONS OF TREATMENT AT 3-YEAR REVIEW

Evaluation	Group 1	2	3
Objective			
A+B	89·8	65·2	36·6
C+D	10·2	34·8	63·4
Subjective			
A+B	93·0	84·8	70·5
C+D	7·0	15·2	29·5

Classes A and B, satisfactory; classes C and D, unsatisfactory.
All figures are percentages.

Group 2: 165 patients in group 2 were treated as outpatients by means of a combination of minor operations followed by postoperative transcutaneous injection/compression therapy. The operations were performed under local analgesia and consisted of flush ligation of the saphenofemoral and/or saphenopopliteal junction and ligation of incompetent perforating veins found by clinical examination.

Group 3: The 157 patients in this group were treated as outpatients by means of injection/compression therapy alone.

The technique used for sclerotherapy was that described in detail by Sigg (1976), and the sclerosant was Aethoxysklerol (hydroxypolyaethoxy-dodecan) in a 3 per cent solution.

Apart from a non-fatal pulmonary embolism occurring in a woman 14 days after bilateral radical operation, only minor complications were seen, and there was no statistically significant difference between the three groups as regards associated complications.

With regard to the period of disability experienced by those patients with jobs outside the home, there was a statistically significant difference between the three groups, the median period of disability being 14·2, 7·6 and 0 days respectively

Observation period and follow-up

The patients were examined and interviewed at th[illegible], at their work or in their home both 3 months and 3 [illegible]r completion of treatment (*Table VI*). At the secon[illegible] 5 patients had died from unrelated diseases and 3 patients were lost, the follow-up therefore being 100 per cent and 98·1 per cent complete at the respective times, without any statistically significant difference between the three groups.

Results of treatment

Treatment was evaluated both objectively and subjectively according to the following criteria:

Objective evaluation

Class A: No visible or palpable varices.

Class B: A few visible or palpable varices with diameter less than 5 mm.

Class C: Remaining or newly formed varices with diameter over 5 mm, main trunks and incompetent perforating veins eliminated.

Class D: Main trunks and/or incompetent perforating veins present.

Subjective evaluation

Class A: No inconvenience.

Class B: Slight functional or cosmetic imperfection, but satisfaction with the result.

Class C: Appreciable functional or cosmetic failure; an improvement compared with the condition before treatment, but dissatisfaction with the result.

Class D: Unaltered or greater inconvenience.

For statistical reasons the results of treatment were evaluated individually for each extremity and, in patients with bilateral varices, one extremity was eliminated by ballot. A Kruskal–Wallis test showed the results of radical operation at 3 years after treatment to be significantly better than those of combined treatment ($P < 0{\cdot}0005$) and combined treatment to be significantly better than sclerotherapy alone ($P < 0{\cdot}0005$).

Table VII shows the relationship between the objective and subjective evaluations, and *Tables VIII* and *IX* show the results of treatment at the first and second review in a simplified form.

Thirty-five patients were examined and interviewed independently by another investigator* whose evaluations were slightly more positive than the author's, but the relationship between [illegible] groups was exactly the same.

Discussion

The treatment has been carried out by a general surgeon with special interest in the treatment of venous disorders and experience in sclerotherapy, but it is not possible to define the degree of expertise with which the surgery and the sclerotherapy have been performed.

The period of observation is not significantly different with regard to the three groups. In all three groups the number of satisfying results of treatment declined between 3-month to 3-year follow-up, but the difference was significantly less for radical operation than combined treatment, and significantly less for combined treatment than sclerotherapy alone. There is no reason to assume that these relationships should change after a longer follow-up.

In a well-controlled trial Hobbs (1974) found similar results, and it can be concluded that saphenous varices are best treated by a radical operation, in spite of the fact that the period of disability following surgery is significantly longer than after sclerotherapy.

[illegible] vity of varicose veins

[illegible] . BROWSE*

SUMMARY

The plasma fibrino[illegible] n, p[illegible] lytic ac[illegible] nolytic a[illegible] hand, g[illegible] forating veins ha[illegible] been stud[illegible] skin changes in the lower leg seco[illegible] sease (lipodermatosclerosis), [illegible] pa[illegible] with uncomplicated varicose veins and in [illegible] normal volunteers undergoing surgery. There was significantly more vein wall fibrinolytic activity in normal volunteers than in the patients with lipodermatosclerosis, not only in the ankle ($P < 0{\cdot}001$) but also in the hand ($P < 0{\cdot}05$).

It is suggested that the reduced tissue fibrinolytic activity is a causative factor in the skin changes and ulceration of the post-phlebitic leg, and that since the reduced activity is not confined to the leg, it may be a primary systemic defect rather than a state secondary to venous congestion.

IN 1959 Todd demonstrated that the vein wall is an important source of plasminogen activator, and modifications of his technique for measuring the vein wall fibrinolytic activity have been used in a number of subsequent studies of venous disease (Pandolfi et al., 1967).

It has been shown by Pandolfi et al. (1967) and by Browse, Gray et al. (1977) that the vein walls are deficient in fibrinolytic activity in patients with recurrent venous thrombosis, and Burnand et al. (1976) have shown that the prolonged venous hypertension in post-phlebitic lipodermatosclerosis causes leakage of fibrinogen through the capillaries and the development of an extravascular pericapillary fibrin 'cuff'.

The purpose of this study was to ascertain whether vein wall fibrinolytic activity in the peripheral veins of patients with venous incompetence is abnormal and whether it is related to the severity of the disease.

Patients and methods

Twenty patients with varicose veins have been investigated—10 with primary long saphenous incompetence and normal skin (mean age of 40 years) and 10 with severe lipodermatosclerosis (mean age of 55 years). Two patients from each group had previously suffered minor episodes of superficial thrombophlebitis in the legs. One patient with primary uncomplicated varicose veins gave a definite history of deep vein thrombosis. The patients with uncomplicated varicose veins had a shorter history of varicosities (mean 18·8 years) than the patients with skin changes (mean 29 years).

Normal veins were obtained from 17 patients (mean age 57) undergoing surgery for local diseases (e.g. gallstones, hernia, peptic ulcer) which, as far as we know, do not affect the vein wall fibrinolytic activity.

Patients with a history of arteriosclerosis of neoplastic disease and patients with a raised preoperative plasma triglyceride or cholesterol were excluded since these abnormalities are shown to be associated with abnormal fibrinolysis. The haemoglobin concentration, platelet count and erythrocyte sedimentation rate of all the patients studied were within the normal range.

A sample of venous blood was taken from the antecubital fossa to measure the plasma fibrinogen concentration and the dilute blood clot lysis time (DBCLT) on the morning following admission (between 9.30 and 10.0 a.m. with the patient fasting). Another sample of blood was taken after 10 min of venous [illegible]gestion using a pneumatic cuff inflated to a pressure of [illegible] Hg to measure 'fibrinolytic capacity' (Robertson et al., [illegible]

The plasma fibrinogen concentration was then estimated with the technique described by Ingram (1952) and DBCLT was measured by Fearnley's method (Fearnley et al., 1957).

Segments of vein 1 cm in length were removed with a minumum of trauma by one author (J. H. N. W.) after induction of general anaesthesia and before surgery. In this way any effects of anaesthesia were standardized. Specimens were taken from the hand, groin, knee and ankle veins of all 20 patients. In 15 patients segments were also removed from both competent and incompetent lower leg perforating veins, competence having been assessed by the Turner-Warwick or 'bleed back' test (Turner-Warwick, 1931). The other 5 patients did not have perforating vein exploration. In the control group the segments of vein were removed from the hand and foot and, at herniorrhaphy, from the groin.

The distal specimens were taken first to avoid distending the segment of vein to be biopsied before removal, since this is known to enhance fibrinolysis (Tighe and Swan, 1963). For the same reason hand vein biopsies were not taken from the arm used by the anaesthetist for recording blood pressure and administering drugs. Two specimens were taken from the groin of patients with varicose veins, one from the long saphenous vein and the second from an adjacent small tributary to see if the size of the vein affected the measurement of tissue fibrinolytic activity.

Vein wall fibrinolytic activity was scored by a modification of the Todd technique described by Browse, Gray et al. (1977). The maximum possible score was 54.

Since the variances differed the validity of using the Student's t test was checked using the variance ratio test. It was subsequently necessary to use the non-parametric Mann–Whitney U test when comparing vein wall activity in the foot (*see Fig.* 3) but in the other comparisons Student's t test was valid and used in preference. Differences between the results of the various groups were considered to be statistically significant if the P value was 0·05 or less.

The purpose of the experiment was explained to the patients and their written consent to venepuncture and vein biopsies obtained.

Results

Vein wall activity

The vein wall fibrinolytic activity in the biopsies taken from the 20 patients with varicose veins is shown in *Fig.* 1. There was a significant difference between the groin and ankle specimens ($P < 0{\cdot}01$). There was no significant difference between the activity of hand and groin specimens. The difference between the groin and knee specimens was significant ($P < 0{\cdot}01$).

Fig. 2 shows the vein wall fibrinolytic activity of these patients subdivided into those with lipodermatosclerosis and those with normal skin. It can be seen that the mean activity of the former was always lower than the mean activity of the latter. The difference at the ankle was significant ($P < 0{\cdot}01$). *Figs.* 1 and 2 also show that the fibrinolytic activity of the wall of the long saphenous vein gradually increases as it ascends to the groin.

Fig. 3 compares the foot vein fibrinolytic activity of those patients with varicose veins with that of the 17 normal subjects. There was a significant difference

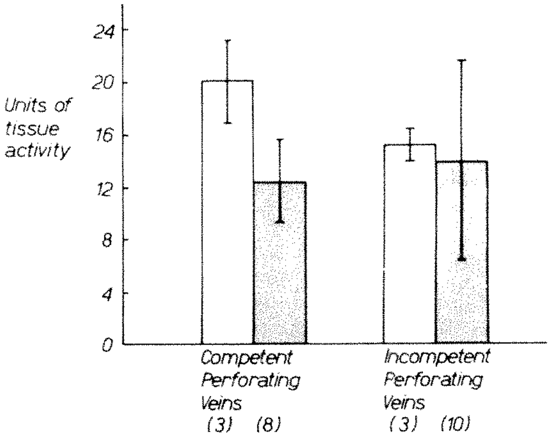

Fig. 5. Fibrinolytic activity of competent and incompetent perforating veins in 15 patients with complicated (shaded) and uncomplicated (white) varicose veins (mean ± s.d.).

between the patients with lipodermatosclerosis and the normal subjects ($P < 0.02$) and those with primary varicose veins ($P < 0.05$). It is of interest that a similar trend was seen in the hand (*Fig.* 4), although this only reached significance when comparing normal volunteers with patients with lipodermatosclerosis ($P < 0.05$).

Since the size of the veins being studied varied, we compared the activity of the main long saphenous vein in the groin (8 mm diameter) with the activity of a small tributary (2 mm diameter) at the same level (19 pairs). The mean activity of the tributaries was 23·4 units and of the long saphenous vein 20·3 units, a statistically insignificant difference. We therefore concluded that it was unnecessary to take into account the diameter of the vein when assessing the results.

Fig. 5 compares the fibrinolytic activity of competent and incompetent perforating veins obtained from patients undergoing a surgical exploration of these veins. There was no significant difference in activity between the two groups. The mean fibrinolytic activity of all incompetent perforating veins was 14·6 units, and of all competent perforating veins, 14·8 units. These values show that the perforating veins do not have any special degree of fibrinolytic activity and fit the general pattern of a graded reduction in activity towards the ankle, as shown in *Fig.* 1. We were unable to make a statistical comparison of the activity of the perforating veins in patients with uncomplicated varicose veins with that in patients with lipodermatosclerosis because of the small number of calf explorations carried out on the former group.

Blood fibrinolytic activity

There was no significant difference between the resting venous blood fibrinolytic activity in the arms of the patients with varicose veins and in the normal volunteers. The increase in arm blood fibrinolytic activity produced by venous congestion in the patients with lipodermatosclerosis and in those with uncomplicated varicose veins was the same. The mean fall in DBCLT in the former group was 54 per cent and in the latter group 52 per cent.

Discussion

These results show that patients with venous valvular incompetence have abnormal vein wall fibrinolytic activity and that this is related to the presence of the skin and subcutaneous tissue changes called lipodermatosclerosis. Burnand et al. (1976) have demonstrated a fibrin 'cuff' around the dermal capillaries in areas of lipodermatosclerosis and suggest that this layer of fibrin may be impervious and lead to tissue necrosis and ulceration. The development of the extravascular cuff of fibrin may be related to a primary pre-existing defect of tissue fibrinolysis, or to the depletion of a previously normal vein wall fibrinolytic activity following the prolonged leakage of fibrinogen from the capillaries and the body's attempt to clear it away.

The diminution of vein wall fibrinolytic activity is not localized to the involved leg. In patients with lipodermatosclerosis the vein wall activity in the hand is also reduced. This suggests that these patients have a primary generalized deficiency of vein wall fibrinolysis; or alternatively that the venous disease in one lower limb can deplete the plasminogen activator in the vein walls of the upper limb.

It is generally taught and believed that lipodermatosclerosis is a sequel to previous deep venous thrombosis. It may be that the deficiency in fibrinolysis plays a causative role in the original thrombosis.

Despite the reduced vein wall activity, the fibrinolytic response in the arm to venous occlusion was the same in the control and the test subjects. In previous studies of larger groups of patients, however, the arm venous blood fibrinolytic activity of patients with lipodermatosclerosis has been found to be below normal (Browse, Jarrett et al., 1977).

Prolonged venous hypertension secondary to valvular incompetence increases the tendency for fibrinogen to leak out of the capillaries and necessitates an increase in fibrinogen clearance from the interstitial spaces (Burnand et al., 1976). Since it is often impossible to cure the venous incompetence, treatment might be directed towards increasing the clearance of interstitial fibrin by stimulating the fibrinolytic system. It is well known that elevation of the limb accelerates the healing of venous ulceration, and Karaca and Nilsson (1971) have found that prolonged bed rest raises the level of leg vein wall fibrinolytic activity to a level similar to that of the arm. This might partially explain the beneficial effect of bed rest on venous ulceration. Stanozolol has been shown to enhance fibrinolysis and a preliminary report by Browse, Jarrett et al. (1977) suggests that this has therapeutic value in the treatment of post-phlebitic lipodermatosclerosis. Overall, there is increasing evidence that a deficiency of the fibrinolytic system plays a role in the aetiology of lipodermatosclerosis and it may be as important a causative factor as the abnormal venous hypertension.

Randomized controlled trial of cefuroxime for established postoperative respiratory infection

J. C. LITCHFIELD, M. R. B. KEIGHLEY, I. W. MYATT
AND M. C. EDWARDS*

SUMMARY

A randomized controlled trial has investigated the value of cefuroxime (a new antibiotic resistant to β-lactamase) in 80 patients with established postoperative respiratory infection. Although the majority of respiratory isolates were sensitive to cefuroxime, there was no significant advantage in the antibiotic group compared with the controls with respect to duration of fever, radiological abnormality or infected sputum. We conclude that antibiotics are rarely necessary for the majority of patients who develop postoperative respiratory infections.

POSTOPERATIVE respiratory sepsis and atelectasis are frequent complications of upper abdominal operations, particularly in the elderly, heavy smokers and patients with chronic bronchitis (Cahill, 1968; Weightman, 1968; Munro, 1970). It has been suggested that antibiotics might be useful in preventing these complications, but they only occur in a minority of patients. Little is known of the value of deferring antibiotic therapy until respiratory complications have become established (*British Medical Journal*, 1977). *Haemophilus influenza* and *Streptococcus pneumoniae* are the pathogens most frequently isolated from the respiratory tract after operation and they are usually sensitive to the broad spectrum penicillins and the cephalosporins (Cavanagh et al., 1976; O'Callaghan et al., 1976). The aim of this study has been to investigate whether antibiotics are of any value for the management of established postoperative respiratory infection. On account of the emergence of bacteria that destroy antibiotics by the production of β-lactamase (Howard et al., 1978), the antibiotic chosen for this trial was cefuroxime, which is resistant to destruction by β-lactamases (Gomme, 1977).

Patients and methods

Eighty consecutive patients who developed postoperative respiratory sepsis were studied. Two of the following three criteria were necessary for admission into the trial: fever greater than 38 °C, purulent sputum or evidence of a new radiographic abnormality compared with the preoperative chest radiograph. All patients received twice-daily chest physiotherapy (breathing exercises, frappage, postural drainage), but nebulizers, ventilators or oropharyngeal suction were not used. In addition to the physiotherapy regimen, 41 patients received cefuroxime while the remaining 39 were given no antibiotic (controls). The allocation of patients to cefuroxime or no antibiotic was based upon random numbers. Cefuroxime was given by intramuscular injection in a dose of 750 mg three times a day.

Response to therapy was evaluated by duration of fever, persistence of infected sputum and duration of radiographic abnormality. Sputum samples were cultured on the third and fifth day. Chest radiographs were repeated on the third and fifth day and were reported by a single radiologist who was unaware whether or not the patient was receiving cefuroxime. Assessment of respiratory function by vitalograph was abandoned because results were not reproducible after recent major surgery. A subjective assessment of response to therapy was also recorded by one of the physiotherapists who did not know into which group the patient had been allocated. Sputum was collected in sterile jars during physiotherapy. The mucus was digested by adding an equal volume of trypure-pancreatin mixture and cultured at 37 °C on blood agar. MacConkey's agar and chocolate agar under aerobic conditions only. Organisms were identified by Gram-stain, appearance of colonies and biochemical reactions. Samples of sputum were stored at 4 °C for batch antibiotic assay using the plate diffusion method.

Patients were excluded if any therapeutic antibiotic had been given before entry into the trial or if prophylactic antimicrobials had been used before or during operation.

Results

The treatment and control groups were similar with respect to criteria for entry into the trial—age, sex, cigarette consumption, nature of operation and previous history of respiratory disease (*Table I*). Despite strict clinical criteria for diagnosis of respiratory infection and evidence of radiographic abnormality in 72 patients (90 per cent), only 47 patients (59 per cent) had respiratory pathogens identified on sputum culture. The predominant organisms in both groups were *Haemophilus influenzae* and *Streptococcus pneumoniae* (*Table II*).

Table I: COMPARISON OF GROUPS

	Cefuroxime ($n = 41$)	No antibiotic ($n = 39$)
Fever more than 38 °C	39 (95%)	37 (95%)
Purulent sputum	41 (100%)	37 (92%)
Radiographic signs	37 (90%)	35 (90%)
Mean age (yr)	49	47
Male	10 (25%)	11 (28%)
More than 20 cigarettes per day	20 (49%)	13 (33%)
Previous chronic respiratory disease	7 (17%)	6 (15%)
Operation		
Gastric	26	22
Biliary	3	8
Colorectal	6	4
Others	5	3

Table II: MICRO-ORGANISMS ISOLATED FROM SPUTUM

	Cefuroxime	No antibiotic
26 *Haemophilus influenzae*	16	10
24 *Streptococcus pneumoniae*	10	14
2 *Klebsiella aerogenes*	—	2
2 *Klebsiella pneumoniae*	1	1
5 *Escherichia coli*	1	4
2 *Proteus* spp.	2	1
3 *Pseudomonas aeruginosa*	3	—
7 *Staphylococcus aureus*	4	3

The numbers of patients with persisting pyrexia after 3 and 5 days were similar in both groups. Radiographic changes were still present at the end of therapy (5 days) in 38 per cent of the treated group

Fair	8	19	9	23
Poor	7	17	8	20

compared with 48 per cent of the controls. The sputum remained infected 5 days after starting treatment in 23 per cent of the antibiotic group compared with 33 per cent of the controls. A subjective assessment of response to therapy indicated that the clinical response was similar in both groups (*Table III*).

The results were also analysed in the 13 patients with severe pre-existing respiratory sepsis. Persistent fever was recorded at the end of treatment in 2 of the 7 patients receiving cefuroxime compared with 1 of the 6 controls. Persistent infected sputum at 5 days was also recorded in 2 of the 7 treated patients compared with 2 of the 6 controls.

Additional antibiotic therapy was used in 8 patients because of failure to respond to the trial regimen; 3 were patients receiving cefuroxime, the remaining 5 patients were in the control group. Three patients in the trial died; in 2 death was due to advanced malignancy but 1 patient not receiving antibiotics developed overwhelming respiratory failure requiring ventilation and died despite subsequent antibiotic therapy.

All of the respiratory isolates with the exception of *Pseudomonas aeruginosa* and one strain of *P. mirabilis* were sensitive to 30 mg discs of cefuroxime. The concentration of cefuroxime in the sputum in patients receiving therapy ranged from 0 to 4·7 μg/ml (mean 0·74 μg/ml).

Discussion

This trial has indicated that most patients who develop respiratory complications after abdominal operations respond satisfactorily to physiotherapy alone. The addition of cefuroxime, an antibiotic shown to be effective against almost all respiratory pathogens, rarely gave any additional benefit to patients. However, the general trend of these results suggests that the patients receiving cefuroxime fared slightly better than the controls, even though statistical analysis failed to demonstrate any significant advantage in the antibiotic group. Analysis of the results, even amongst patients with severe pre-existing respiratory infection, in whom prophylactic antibiotics would normally be advised (Dudley et al., 1962), showed that patients receiving antibiotics did not appear to show any improvement over those treated with physiotherapy alone.

With the exception of *P. aeruginosa* and *Proteus* spp., all other respiratory isolates were sensitive to cefuroxime. Even after 5 days' treatment, however, 5 patients still had sensitive bacteria isolated from the sputum. Cefuroxime levels in sputum rarely exceeded the minimal inhibitory concentration for most respiratory pathogens, which is in accordance with the results of other studies (Pines et al., 1977). These results suggest, therefore, that systemic therapy may not always be appropriate in patients with postoperative respiratory sepsis.

Although there were no drug-induced complications with cefuroxime, a course of injections lasting 5 days was frequently reported by patients to be painful. For this reason we would not recommend antibiotics routinely for established postoperative respiratory sepsis since improvement can be expected with physiotherapy alone in most patients.

It could be argued that with greater numbers a significant difference between the groups might have been achieved. An earlier analysis of the results suggested that cefuroxime might prove to be effective therapy, but at that stage the groups were poorly matched for age and type of operation (Keighley and Litchfield, 1978). It was felt that a total of 80 patients would probably demonstrate an important difference if one was present. The analysis of the present data does not support the earlier findings and indicates that antibiotics have little place in the management of postoperative chest infection.

There is also very little evidence that preoperative prophylactic antibiotics reduce the incidence of postoperative respiratory sepsis (Laszlo et al., 1973; Presley and Alexander-Williams, 1974). Furthermore, this study and others indicate that respiratory complications are frequently transient and respond to physiotherapy (Collins et al., 1968) and that many patients with postoperative respiratory complications have atelectasis without bacterial infection in the sputum. Because of the dangers of unnecessary antibiotic therapy (Garrod, 1972), we would not recommend routine prophylaxis for all patients and would advise that antibiotic prophylaxis be reserved for patients with pre-existing respiratory sepsis or cardiorespiratory failure.

NOW

FLAGYL

METRONIDAZOLE

INJECTION

FOR INTRAVENOUS INFUSION

proves decisive in anaerobic infections

Only with recent improvements in bacterial culturing techniques has the pathogenic role of anaerobes in post-surgical infections been fully recognized.[1-3] Now 'Flagyl' Injection offers you a decisive means of treating these infections – which are often life-threatening and often resistant to established antimicrobials. The response to 'Flagyl' Injection is rapid a dependable,[2] as it is consistently bactericidal to pathogenic anaerobes at t concentrations easily achieved in treatment. Bacterial resistance is not a pro and 'Flagyl' is highly acceptable – as eighteen years of use in other indications has

age: Treatment: adults and children over 12 years: 100 ml by intravenous sion eight-hourly, administered 5 ml per minute. Oral medication with 400 mg e times daily should be substituted as soon as this becomes feasible. Treatment even days should be satisfactory in most cases. Children under 12 years: as dults but the single intravenous dose is based on 1.5 ml (7.5 mg ronidazole) per kg bodyweight and the oral dose on 7.5 mg per kg bodyweight. ention: adults and children over 12 years: 100 ml by intravenous infusion ediately before, during or after operation, followed by the same dose eight- ly until oral medication (200 to 400 mg three times daily) can be given to plete a seven-day course. Children under 12 years: as for adults but the single venous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight the oral dose on 3.7 to 7.5 mg per kg bodyweight. Precautions: pregnancy; ation; clinical and biological surveillance if recommended duration of treatment eded; dosage may be halved for patients with renal failure; avoid alcohol; if yl' is to be given to patients receiving oral anticoagulants the dosages of the r should be recalibrated. Side effects and adverse reactions: occasionally an easant taste, furred tongue, nausea, vomiting (very rarely), gastro-intestinal rbance. Drowsiness, dizziness, headache, ataxia, skin rashes, pruritus, ordination of movement, darkening of the urine very rarely. During intensive or prolonged therapy, peripheral neuropathy has been reported. A moderate penia has been reported but the white cell count has always returned to al before or after treatment has been completed. Transient epileptiform seizures in a few patients undergoing intensive, high-dosage metronidazole radiosensitization therapy.

[illegible] *a.* [illegible] *ne patients receive* [illegible] *alazole and 59 received Thalazo* [illegible] *curred in 8 (13·1 per cent) of the 61 pati* [illegible] *received metronidazole, compared with 29 (49·2 per cent) of 59 patients who received only Thalazole. Of the 8 patients with sepsis who received metronidazole, none had infection due to anaerobic organisms.*

IT has been known for over a decade that nearly 80 per cent of the faecal flora consists of *Bacteroides* species (van Houte and Gibbons, 1966). It is, however, only recently that attention has been drawn to the use of antibiotics with specific action against these anaerobic organisms in the preparation of the bowel for surgery (Willis et al., 1977). Any major advance to be made in the control of postoperative sepsis following bowel surgery would clearly lie in the choice of an antibiotic effective against anaerobic organisms. With this in mind we designed a trial comparing two groups of patients undergoing colonic resection, in which one group received the antibiotic metronidazole, which is strictly effective against anaerobic organisms. The preliminary results (Taylor and Cawdery, 1977) indicated that a reduction in the wound sepsis rate could be achieved using such an antibiotic. The decision whether to give the control group an antibiotic or not was difficult. Recent observations (*British Medical Journal*, 1976) have suggested that all that is required for adequate bowel preparation is mechanical cleaning. When we planned the study, however, we relied upon the earlier observations of Rosenberg et al. (1971), which indicated that mechanical cleaning alone was inferior to the addition of Thalazole to the regimen. We accordingly used Thalazole to minimize the risk to our patients.

Patients and methods

Patients in whom colonic resection was planned were randomized into two groups by a secretary who selected an appropriately labelled card. Patients in group A received oral Thalazole 2·5 g four times a day for 4 days, while those in group B received oral metronidazole 400 mg three times a day for 4 days in addition to Thalazole in the same dosage, i.e. 2·5 g four times a day. In both groups the bowel was prepared mechanically in an identical way and an oral elemental diet was given during the 4 days of preparation, so that only the antibiotic treatment varied. Antibiotic cover was not extended into the postoperative period. After operation the wound was inspected at intervals determined by the surgical team in charge of the patient and any inflammation or sepsis was recorded using the criteria of Ljungqvist (1964) and a bacteriological swab was taken for aerobic and anaerobic culture. Twenty patients from each group were studied for change in faecal flora by taking a bacteriological swab from the lumen of the specimen after resection and setting it up for aerobic and anaerobic culture.

In all, 126 patients were allocated to the trial. There were 6 exclusions—4 from group A and 2 from group B—for reasons of inoperability or the use of a systemic antibiotic in the early postoperative period. The age range of the group A patients [illegible]s 26–80 years (mean 60) and that of 34–79 years (mean 57). There were 2 patients in group A and 20 male and group B.

Statistical analysis was performed usi paired alternatives.

Results

Results of faecal sampling

The results from 40 patients (20 show that the incidence of anae group B patients was significantly with group A patients. Only 2 p grew anaerobes from the faecal sa patients from group A. The ana in group B patients were clostridi less sensitive to metronidazole th organisms.

Postoperative sepsis

Of the 120 patients eligible for st group A and 61 from group B. 49·2 per cent in group A and 13· is a significant reduction in sepsis Perineal sepsis occurred more fre patients (10 out of 15 *v*. 6 out of 1 was not statistically significant patients in group A who had a the rectum showed a much higher sepsis than those in group B (*Ta* *v*. 2 out of 31) and the difference 0·001).

(*Escherichia coli*, *Streptococcus faecalis* and *Staphylococcus aureus*) tended to be less ill and the wound discharge was noted to be less copious and less offensive.

Two patients from each group sustained deep pelvic infection following anterior resection of the rectum with discharge of pus from the drain site and per rectum. All had associated infection of the abdominal wound. Two group A patients had septicaemic episodes in the postoperative period. In one a *Bacteroides* sp. was grown on blood culture and treatment with metronidazole was effective. The infection appeared to arise from coexistent pelvic and wound infections.

Discussion

There is evidence that the addition of metronidazole to a standard bowel preparation reduces the rate of wound sepsis after operation. It is also evident that the drug is effective in eliminating infection due to anaerobic organisms. (*Table II.*) In group A there were 17 instances of infection due to *Bacteroides* spp. and none in group B patients ($P < 0{\cdot}001$). It also seems that prophylaxis with the drug is only required during the preoperative preparation of the patient for the elimination of infection due to anaerobic organisms. Its use therefore need not be extended into the postoperative period. Metronidazole is entirely selective in its effects on anaerobic organisms and is completely inactive against aerobic bacteria (Willis et al., 1977). It appears to be non-toxic when used for short periods and at low total dosage. The results obtained in our series suggest that in some way anaerobic organisms work in synergism with aerobic organisms to produce their effects in the wound. Removal of the anaerobes alone may be all that is required to reduce sepsis and it may be unnecessary to add another antibiotic effective against Gram-negative bacteria (Goldring et al., 1975). Recent information supporting this hypothesis comes from Ingham et al. (1977), who provide evidence that *Bacteroides melaninogenicus* and *B. fragilis* interfere with the phagocytosis and killing of *P. mirabilis* and other aerobic bacteria *in vitro*, thus rendering them pathogenic. This could explain why agents such as Thalazole used alone, as in our control group, are

o[illegible]
wh[illegible]
tive [illegible] note that in group B pa[illegible]
it was [illegible] und which became infected and not the [illegible] ominal incision, whereas those patients in group A who developed perineal wound infection also had infected abdominal wounds.

These results are an improvement on those of other quoted series in which lincomycin was given (Downing et al., 1977). The use of improved methods of cleansing the bowel by mechanical means is now well established (Crapp et al., 1975). This, in conjunction with meticulous surgical technique and the elimination of anaerobic organisms from the resected colon, serves to improve the sepsis rate after colonic surgery.

Acknowledgement

We are grateful to the surgeons of King's College Hospital, London, and the Brighton Hospitals for allowing us to study their patients.

One-dose antibiotic prophylaxis against wound infection after appendicectomy: a randomized trial of clindamycin, cefazolin sodium and a placebo

I. A. DONOVAN, D. ELLIS, D. GATEHOUSE, G. LITTLE,
R. GRIMLEY, S. ARMISTEAD, M. R. B. KEIGHLEY AND C. J. L. STRACHAN*

SUMMARY

Two hundred and fifty patients were admitted to a prospective randomized trial of single dosage prophylaxis against wound infection after appendicectomy. There were 12 exclusions, 72 patients received placebo, 81 received 600 mg i.m. clindamycin phosphate and 85 received 1 g i.m. cefazolin sodium, the agent being given in the anaesthetic room. Clindamycin produced a significant reduction in the overall rate of wound infection from 33 per cent in the controls to 17 per cent. In cases with a gangrenous or perforated appendix the infection rate in controls was 78 per cent; this was reduced to 44 per cent by a single dose of clindamycin.

Cefazolin significantly reduced the number of aerobic organisms isolated from wound infections, but did not significantly reduce the incidence of wound infection. We conclude that anaerobic organisms are more important than faecal aerobic organisms in the pathogenesis of wound infection after appendicectomy.

WOUND infection has been reported to occur in up to 30 per cent of all patients after appendicectomy (Bird et al., 1971), and the incidence may be as high as 63 per cent in perforated appendicitis (Leigh et al., 1974).

Leigh and his colleagues (1974) found bacteroides in 78 per cent of their isolates from swabs of the appendix fossa taken at appendicectomy. One of the most active antibiotics against bacteroides is clindamycin (Kislak, 1972; Sutter, 1977), which became available in parenteral form as clindamycin phosphate in Great Britain in 1976. A prospective trial of clindamycin phosphate was therefore undertaken to determine its efficiency against wound infection after appendicectomy. In the present trial we have compared clindamycin with an antibiotic whose main activity is against the faecal aerobic organisms. Cefazolin sodium has been shown by Strachan and his colleagues (1977) to be a very effective prophylactic against wound infection after cholecystectomy even when given as a single dose, and we therefore decided to use this agent in a similar regimen in cases of appendicitis. From this trial we hoped to determine whether anaerobic or aerobic organisms were the most important in the genesis of post-appendicectomy wound infections.

Patients and methods

A prospective randomized trial of cefazolin sodium, clindamycin phosphate and placebo was established. Randomization was based on a table of random numbers. A single dose was given by intramuscular injection to the anaesthetized patient in the anaesthetic room. The patient received 600 mg of clindamycin phosphate or 1 g of cefazolin sodium or 3 ml of placebo. The phials were identified by a code number. The trial was conducted in several centres, 4 hospitals entering a total of 250 patients into the study. Excluded from entry to the trial were children under the age of 12 years, patients who had received antibiotics within the previous 7 days before operation and patients with a history of penicillin allergy.

In each hospital there was an assessor who inspected the wounds. Wound sepsis was defined as the discharge of pus from the wound either spontaneously or after incision. All patients were given a follow-up appointment for wound inspection by the assessor 2–3 weeks after operation.

A numbered form was provided, the number on the form corresponding with a numbered phial of drug or placebo kept in the theatre refrigerator. The surgeon was asked to record the incision, the presence and nature of intraperitoneal fluid, the macroscopic appearance of the appendix, the use and siting of drains and the use of peritoneal lavage with normal saline. The use of topical antibiotics or antiseptics in the peritoneal cavity or the wound was prohibited.

At operation the appendix was divided and half was sent for histopathology and half was placed in transport medium for microbiology. Emergency microbiology was not feasible. Aerobic and anaerobic cultures of the appendix were prepared during normal working hours. Pus from wound infections was collected and taken immediately to the microbiology laboratory for aerobic and anaerobic culture. Unfortunately, specimens were not usually obtainable from patients whose wounds became purulent after hospital discharge.

The cultures for anaerobic organisms were made on selective media (Rogossa agar and lysed blood agar containing menadione), and were cultured either in an anaerobic chamber or in anaerobic jars for 7 days. The details of the method varied slightly from hospital to hospital.

Results

The trial was opened in December 1976 and closed 12 months later, at which time 250 patients had been admitted. There were 12 withdrawals either due to other pathology being present (7 patients) or due to the addition of antibiotics within 48 h of operation with no subsequent development of wound infection (5 patients).

Of the residual 238 patients, 72 received placebo, 81 received clindamycin and 85 cefazolin. The overall infection rates in the three groups are shown in *Table I*. The statistical test applied throughout in this paper was the χ^2 test with the Yates' correction. There are a number of high risk factors which may produce unfavourable bias in overall figures in appendicitis. The most important of these are the state of the appendix (Leigh et al., 1974), the use of drains (Brumer, 1970) and the age of the patient (Kingsley, 1969).

On the basis of the surgeon's opinion at operation and on histological examination, the appendix was graded as normal, acutely inflamed and perforated or gangrenous. The distribution of these grades in the three trial groups is shown in *Table II*. There was a greater proportion of perforated or gangrenous appendices in the cefazolin group compared with

both the clindamycin and the placebo group, the latter having the lowest proportion of all. We have, therefore, examined the rate of wound infection in the gangrenous or perforated group separately (*Table III*). The rates of wound sepsis in the placebo and cefazolin group were virtually identical but that in the clindamycin group was significantly lower ($\chi^2 = 5{\cdot}05$, $P < 0{\cdot}025$).

The incidence of wound sepsis in the normal and acutely inflamed groups is shown in *Table IV*. Despite considerable percentage variation in infection rates, no significant differences were demonstrable on statistical analysis because the numbers in the subgroups are small. However, the distribution of cases is comparable in the three trial groups with regard to normal and acutely inflamed appendices and if these categories are considered together, clindamycin produced a significant reduction in wound infection compared with the placebo ($\chi^2 = 5{\cdot}3$, $P < 0{\cdot}025$); cefazolin produced no significant effect.

Drains were used in 12 of the placebo group, 14 of the clindamycin group and 15 of the cefazolin patients, a total of 41 out of 238 patients. Twelve of these were in cases of acute appendicitis, of whom 3 developed wound infection, all in the placebo group. Of the remaining 29 in the gangrenous or perforated category, 3 of 5 in the placebo, 13 of 14 in the cefazolin and 8 of 10 in the clindamycin group developed wound infections. These numbers are too small to permit any comment other than that the incidence of drainage in cases of gangrenous perforated appendix was 56 per cent in all three trial groups so that there is no evidence of bias.

Table V shows the infection rates in patients over the age of 40 with regard also to the state of the appendix. There is no obvious bias in favour of any group.

There were 5 more severe septic complications; all occurred in patients with a perforated or gangrenous appendix who subsequently developed wound infections. One patient had an ileus lasting for 2 weeks and another had a re-exploration for suspected intra-abdominal pus, although none was found. A third required secondary suture of the wound and a fourth had a pelvic abscess which was drained. One patient died: he was a 74-year-old male chronic bronchitic who had persistent wound and chest infection. He died 3 months after operation of a pulmonary embolism.

Of the 238 patients, 229 had grid-iron incisions and only 9 had right paramedian incisions. No useful analysis was possible on these small numbers and likewise the information on peritoneal lavage with normal [illegible] only 20 patients. The preser[illegible] toneal fluid did not [illegible] elihood of wound [illegible] pparent from the [illegible] frequency of free [illegible] the severity of the [illegible]

[illegible] om the sectioned [illegible] 115 cases, and in [illegible] preparing the cultures, [illegible] for [illegible] as unreliable and are therefore not reporting it. M[illegible]biology was available from 50 of the 68 wound infections. Fifteen (22 per cent) only became manifest after hospital discharge. The incidence of anaerobic and aerobic wound isolates is shown in *Table VII*. Although less anaerobes were grown from infections in the clindamycin group than from the other groups, the difference is not significant, the numbers being too small. There is, however, a significant reduction in the numbers of aerobic isolates from infections in the cefazolin group compared with the others ($\chi^2 = 4{\cdot}6$, $P < 0{\cdot}05$).

Discussion

Previous clinical trials have failed to demonstrate any influence on wound infection when antibiotics are started after operation (McKittrick and Wheelock, 1954; Barnes et al., 1959), and experiments in animals have demonstrated that to provide effective prophylaxis against wound infections the antibiotic must be present in the tissues at the time of operation (Burke, 1961; Alexander-Williams and Altemeier, 1965). We therefore considered that if antibiotics were started more than 48 h after operation, it was unlikely that they would influence development of wound infection, and therefore such patients were not withdrawn from the study. Patients in whom additional antibiotics were started within 48 h of operation were excluded unless they developed a wound infection, in which case the original prophylaxis had failed anyway.

The results of the study show that although an antibiotic active against aerobic organisms was effective in reducing the number of aerobic isolates from wound infections, it had no effect on the incidence of wound infection. An antibiotic effective against anaerobic organisms, however, did significantly reduce wound infections. These findings strongly support the hypothesis that the anaerobic organisms are more important than the facultative aerobes in the production of endogenous wound infection after appendicectomy. The overall reduction in wound infection, however, was not as great as that reported in some other trials, especially those in which topical ampicillin powder has been used (*Table VIII*).

In this trial the wound infection rate in the control group was higher than that in most previously reported series (*Table VIII*), ranging from 20 per cent in the normal patients to 78 per cent in those with gangrenous or perforated appendices. Our finding of 22 per cent of wound infections presenting after hospital discharge is comparable to that of other authors (Gilmore et al., 1973 = 30 per cent; Bates et al., 1974 = 21 per cent). The single dose of clindamycin reduced the incidence of wound infection after removal of a normal appendix from 20 to 4 per cent, providing adequate prophylaxis, and in this group of patients cefazolin also appears to be effective, as the infe[illegible] rate [illegible] only 6 per cent, although the numbers are too small for a statistical comparison.

In acute appendicitis the wound infection rate was reduced from 30 to 13 per cent by clindamycin, no systemic complications of sepsis being seen in any of the three trial groups in acute appendicitis. In cases with gangrenous or perforated appendices the control infection rate of 78 per cent was reduced to the still unacceptably high level of 44 per cent, and more severe complications were seen. In these patients more prolonged antibiotic therapy with clindamycin is required, and it could be argued that systemic cephazolin should also be administered in view of its effect on the aerobic flora, the drug first being given at operation when the severity of the appendicitis has become apparent. In this study the incidence of wound infection in cases described as having gangrenous appendicitis was comparable to the incidence in those cases described as having perforated appendicitis (overall infection rates: gangrenous, 64 per cent; perforated, 70 per cent). We feel justified, therefore, in putting them together as one high risk group.

A single-dose systemic prophylactic regimen, as described here with clindamycin, should produce little risk of the emergence of resistant strains, and is very unlikely to induce pseudomembranous colitis, which is more common when an anti-anaerobic agent is used for longer and in combination with an anti-aerobic agent (Kappas et al., 1978). In this study no cases of pseudomembranous colitis were seen. Three patients developed postoperative diarrhoea and were examined by sigmoidoscopy, but no abnormality was found on biopsy. Two of these patients had received clindamycin and one cephazolin as a single-dose prophylaxis.

Acknowledgements

We are grateful to the consultant surgeons in the four hospitals who very kindly allowed us to enter their patients into the trial, and to all the surgeons who operated upon and looked after the patients. We would also like to thank the microbiologists involved. We are grateful to Eli Lilly for providing the cephazolin sodium and to Upjohn for providing the clindamycin phosphate.

Preventi[illegible] eal adhesions: a comparison of noxythi[illegible] vidone-iodine/PVP solution

O. J. A. GILMO[illegible]

SUMMARY

Peritoneal adhesions were induced in 250 [illegible] rats by the excision and closure of a right lower quadrant parietal peritoneal defect. After closure of the defect each rat was randomly allocated to one of five treatment groups: A, control with no instillate; B, control with Ringer solution; C, noxythiolin 0·5 per cent solution; D, noxythiolin 1 per cent solution; E povidone-iodine/PVP solution. Two millilitres of the appropriate solution were injected into the peritoneal cavity just before closure of a standard 4-cm midline incision. Assessment of adhesion formation was made at 1 week in ignorance of the treatment group. Noxythiolin 1 per cent was more effective than Ringer solution and noxythiolin 0·5 per cent in reducing the mean number of adhesions ($P<0\cdot05$) but was inferior to povidone-iodine/PVP ($P<0\cdot05$). Povidone-iodine/PVP solution significantly reduced the number of adhesions compared with the four other groups. In addition, it significantly reduced the mean length of attachment of each adhesion compared with the two control groups ($P<0\cdot001$).

SINCE the advent of abdominal surgery one of the main aims of the surgeon has been to prevent intraperitoneal adhesions. All surgeons dislike finding adhesions when they explore a patient who has had a previous laparotomy. Ellis (1974) reported a 92 per cent incidence of adhesions in such patients. Abdominal surgery is now so common that the adhesions that it produces are the most frequent cause of small bowel obstruction (Ellis, 1974). Krook (1947) concluded from an extensive study that just under 1 per cent of patients who undergo gynaecological surgery develop intestinal obstruction caused by adhesions: this compares with a figure of 4 per cent for those who have an appendicectomy for a perforated appendix.

Ellis (1962, 1971, 1974) believes the aetiology of adhesions to be ischaemic, whereas Boys (1942) and Krook (1947) indicate infection. Experimental and clinical observations suggest that both are potent causes, but whether infection induces adhesions by means of ischaemia remains uncertain.

Noxythiolin (Noxyflex) is a widely used antiseptic and will significantly reduce adhesion formation in the rat (Gilmore and Reid, 1976). A polyvinylpyrrolidone (povidone/PVP) iodine solution containing 1 per cent PVP and 0·1 per cent available iodine failed to prevent adhesions in rats following colectomy (Gilmore, Rosin et al., 1978). However, 6–7 per cent PVP solutions have been effective in both animals (Kalligianis, 1961; Mazuji et al., 1964; Badowski and Daciewicz, 1971) and man (Oetell et al., 1954; Upplegger, 1956). Recently a newly formulated povidone-iodine/PVP solution containing 11 per cent PVP and 0·1 per cent available iodine has been found to reduce significantly peritoneal adhesion formation in the rat (Gilmore and Reid, 1978).

A safe and effective intraperitoneal antiseptic with anti-adhesive properties has enormous potential in elective and emergency surgery. It was therefore decided to compare the efficacy of noxythiolin and povidone-iodine/PVP in preventing adhesions in a standard animal model (Gilmore and Reid, 1976).

Materials and methods

Povidone-iodine/PVP solution

A mixture of 10 g of dry PVP powder and 1 g of dry povidone-iodine (containing 0·9 g PVP and 0·1 g available iodine) was added to approximately 89 g of sterile water. In order to determine the available iodine content (0·1 per cent was required), the solution was titrated against sodium thiosulphate. More sterile water was added and further titrations performed until the povidone-iodine/PVP solution was demonstrated to contain 0·1 per cent available iodine.

Experimental model

A total of 250 female Wistar rats weighing 150–200 g was used. To avoid the chance deposition of starch granules in the peritoneal cavity all the operations were performed without gloves in clean, but not sterile, conditions.

Peritoneal adhesions were induced by the excision and closure of a standard-size peritoneal defect (Gilmore and Reid, 1976). Under ether anaesthesia, following shaving and skin disinfection, the abdomen of each rat was opened through a 4-cm vertical, midline incision.

An area of parietal peritoneum in the right lower quadrant was then grasped and lifted with a pair of Duval forceps measuring 1·4 cm along their grasping tip. The forceps were adjusted so that the flap of peritoneum reached a point 0·5 cm proximal to the teeth of the forceps. The peritoneum and underlying muscle were incised with a scalpel along all margins of the forceps which, when removed, left a clearly marked window of peritoneum measuring 1·0 × 1·4 cm. This window and the underlying muscle were then excised and the resultant defect closed with continuous atraumatic 3/0 black silk sutures.

All abdominal incisions were closed in two layers. The musculoperitoneal layer was closed with continuous 2/0 chromic catgut and the skin was sutured with continuous 2/0 black silk.

A card was drawn allocating each rat to one of five treatment groups: group A, control, no intraperitoneal instillate; group B, control, 2 ml of Ringer solution; group C, 2 ml noxythiolin 0·5 per cent solution; group D, 2 ml noxythiolin 1·0 per cent solution; group E, 2 ml povidone-iodine/PVP solution. All solutions were injected into the peritoneal cavity just before the insertion and tying of the final musculoperitoneal suture.

Assessment of adhesion formation

All rats were killed at 1 week and an autopsy examination of the abdomen performed in ignorance of the treatment group. A reversed 'C' incision was made along the left side of the abdomen, as the peritoneal defect was on the right. In every rat the following details were recorded: number of adhesions present; length of attachment of each adhesion, measured in millimetres with a ruler; the site of origin of each adhesion and the site of adherence.

Statistical methods

The mean number of adhesions per rat was calculated for each treatment group. These means were then compared using the technique of analysis of variance, since five groups were involved (Armitage, 1973). Distribution curves were drawn for

each treatment group to check that the data were normally distributed. An overall F test of the treatment effects was carried out before comparison of individual pairs of means by an unpaired Student's t test (Armitage, 1973). This gave protection against spurious significant differences arising from the simultaneous comparison of several means.

The average length of adhesions was calculated for each rat. The means for each treatment group were again compared by analysis of variance.

Results

The peroperative intraperitoneal instillation of povidone-iodine/PVP solution gave a statistically significant reduction in the number of adhesions formed in treated rats, compared with all four other groups (*Table I*). Treatment with the povidone-iodine/PVP solution not only resulted in fewer adhesions, but the mean length of attachment of each adhesion was significantly shorter than for either of the two control groups or for group C (*Table II*).

The rats treated with noxythiolin 1 per cent had significantly fewer adhesions ($P<0\cdot05$) compared with groups B and C (*Table I*). The mean length of attachment of each of these adhesions was significantly shorter than that of those occurring in either of the control groups ($P<0\cdot01$) (*Table II*).

Of the 250 rats in the study, 229 developed adhesions. Of the 21 who had no adhesions, 12 were in group E (povidone-iodine/PVP solution) and 8 in group D (noxythiolin 1 per cent). The intraperitoneal instillation of Ringer solution or noxythiolin 0·5 per cent had no effect on the incidence of adhesion formation (*Tables I, II*).

The mean total length of attachment of adhesions per rat (as opposed to the mean length of each adhesion) varied according to the treatment group. Rats in group A had an average 13·3 mm of adhesions, those in group B 14·7 mm, group C 12·3 mm, group D 11·4 mm and group E 6·9 mm.

Throughout the study, all the adhesions seen were either adherent to the peritoneal defect or to the midline abdominal wound. Rats treated with povidone-iodine/PVP solution had fewer adhesions to both sites. Seventy-one rats (28·4 per cent) in the study developed adhesions to the midline laparotomy scar. The incidence of adhesions to this site varied from 14 per cent in the povidone-iodine/PVP group to 46 per cent in the noxythiolin 0·5 per cent group.

The commonest structure found at autopsy to be adherent to either the peritoneal defect or the midline scar was the ovarian complex. The ovary in the rat lies at the end of a long Fallopian tube which has attached to it an abundant broad ligament or mesentery. The entire complex is mobile. The greater omentum was the next most frequently involved with adhesions. Both the broad ligament (mesentery of the Fallopian tube) and the greater omentum are vascular structures and at autopsy new blood vessels were sometimes noted passing from these structures into the closed peritoneal defect or midline scar.

Discussion

This study shows that intraperitoneal instillation of the newly formulated povidone-iodine/PVP solution (PVP 11 per cent, available iodine 0·1 per cent) at operation results in a highly significant reduction in both the number ($P<0\cdot001$) and the mean length of attachment ($P<0\cdot001$) of adhesions forming in treated rats compared with untreated controls. The fact that povidone-iodine (PVP 1 per cent, available iodine 0·1 per cent) had no effect on the development of adhesions in rats following colectomy (Gilmore, Rosin et al., 1978) suggests that the anti-adhesive effect of the new formulation is due to the increased PVP content.

As might be expected from our previous study (Gilmore and Reid, 1976), noxythiolin 1 per cent significantly reduced the number of adhesions in treated rats compared with rats given Ringer solution ($P<0\cdot05$) and also reduced the mean length of adhesions formed ($P<0\cdot01$). Rats treated with noxythiolin 1 per cent, however, had significantly more adhesions ($P<0\cdot05$) than those treated with povidone-iodine/PVP. The fact that noxythiolin 0·5 per cent was ineffective suggests that the anti-adhesive property of this antiseptic is related to its concentration.

It has been clearly demonstrated that it is not simply the presence of fluid in the peritoneal cavity which prevents adhesions forming. There was no significant difference in the number of adhesions between groups A, B or C, yet only rats in the latter two groups received intraperitoneal fluid.

It is difficult to relate the anatomy of the adhesions formed in this study to man. However, it is interesting to note that the greater omentum was frequently involved with adhesions and that 28·4 per cent of the laparotomy incisions had adhesions. How effective the new povidone-iodine/PVP solution would be in preventing intestinal obstruction due to adhesions in man remains a point of conjecture, since its use did not completely eliminate their formation in rats.

There are three possible reasons for the anti-adhesive effect of noxythiolin. O'Meara showed it to have anticoagulant properties, thus preventing fibrin deposition (Garratt, 1969). Its topical cytotoxic

OUR THANKS TO ALL THOSE BRITISH SURGEONS WHO'VE HAD A HAND IN OUR SUCCESS.

For as long as British Surgeons have been wearing latex Surgeons' gloves, we have been making them.

While British medical research and discovery has been improving surgical procedures, ongoing research and improved rubber technology has developed a glove that precisely fits the needs of today's British Surgeon.

The continuing input of suggestions and comments by Surgeons plays a vital part in this evolution and this is why we'd like to thank you, the British Surgeon, for the hand you've had in our success.

ad [illegible] an [illegible] PV [illegible] since [illegible] mo [illegible] Expe [illegible] Goto [illegible] indica [illegible] affect [illegible] division by slow [illegible] contact inhibition, thus cells [illegible] agglutinability. This seems the most likely explanation of the anti-adhesive effect of povidone-iodine/PVP solution. But again, as with noxythioloin, the solution's antiseptic properties probably also played a part.

We have shown in the rat that treatment with a newly formulated povidone-iodine/PVP solution is significantly more effective in reducing the number of peritoneal adhesions forming than is treatment with Ringer solution and noxythiolin 0·5 per cent and 1·0 per cent. A standard povidone-iodine has been shown to reduce significantly the mortality of mice and rats with peritonitis (Gilmore, Reid et al., 1978). It seems unlikely that the newly formulated mixture used in the present study loses its antiseptic properties when the additional PVP is added, since the chemical reaction between PVP and iodine is taken to completion when they are combined initially (Siggia, 1957).

This new solution with its antibacterial and anti-adhesive properties would appear to have considerable potential in all operations involving mesothelial surfaces.

Mercury nephrotoxicity from peritoneal lavage

FLIGHT LIEUTENANT C. D. PUSEY, SQUADRON LEADER [illegible] D. KENNEDY
AND SQUADRON LEADER D. J. RAINFORD*

SUMMARY
Two cases of acute renal failure following intraperitoneal administration of mercury are described.

MERCURIC chloride is a known nephrotoxin, causing renal failure in acute poisoning and nephrotic syndrome following prolonged exposure. In this report we present 2 cases of acute renal failure following intraperitoneal administration of mercury. One patient subsequently developed nephrotic syndrome.

Case reports

Case 1: A 61-year-old woman presented in July 1976 with a history of abdominal discomfort and swelling. At laparotomy she was found to have a large ovarian cyst which ruptured on removal. Because of the possibility of malignancy, peritoneal lavage was performed with a 1 : 2000 solution of mercuric chloride. Postoperatively she became severely hypotensive with abdominal distension. Bleeding was suspected, but repeat laparotomy revealed an intense exudative peritoneal reaction. Urine output fell to 350 ml in the following 24 h despite fluid replacement and high doses of frusemide. The patient was transferred to the renal unit where the diagnosis of established oliguric acute renal failure was confirmed. Mercury levels on admission were raised in serum (12 mmol/l) and urine (1400 nmol/l) (normal urinary level up to 100 nmol/l). The patient's initial blood urea was 24 mmol/l, rising to 36 mmol/l by the fourth postoperative day, when haemodialysis was commenced. She required daily dialysis for 9 days before a diuresis ensued, with a spontaneous fall in blood urea by the eighteenth postoperative day.

The patient's urine was protein-free on discharge, but on routine follow-up in January 1977 she was found to have the nephrotic syndrome. Despite symptomatic treatment with diuretics and salt-poor albumin infusions, urinary levels rose to 53 g/24 h and she became increasingly oedematous. Renal biopsy showed minimal change of the glomeruli and mild interstitial nephritis. She was treated with high dose intravenous methyl prednisolone pulses with a rapid fall in urinary protein. Remission was maintained on oral prednisolone for 6 months and there has been no recurrence of proteinuria since stopping therapy.

Case 2: A 50-year-old woman presented in August 1976 with a history of abdominal pain and altered bowel habit. Barium enema was suggestive of malignancy and laparotomy in October 1976 confirmed a localized carcinoma of the descending colon, for which a left hemicolectomy was performed. Peritoneal lavage with a 1 : 500 solution of mercuric chloride was carried out. Postoperatively she became severely hypotensive with signs of peritonitis. Resuscitative measures restored cardiovascular stability, but urine output remained fixed at between 1 and 1·5 l/24 h and was of low and inappropriate osmolality. Blood urea rose to 46 mmol/l by the tenth postoperative day and established non-oliguric acute renal failure was diagnosed. The serum mercury level when the patient was first seen was 11·9 mmol/l. A mobile dialysis team from the renal unit commenced haemodialysis. Daily dialysis was required for 6 days before a diuresis ensued, with a spontaneous fall in blood urea by the nineteenth postoperative day. There has been no significant proteinuria on follow-up to date.

Discussion

These two cases illustrate the potential hazard of peritoneal lavage with mercuric chloride. This technique has been used for many years in the belief that mercury exerts a cyt[illegible] on any malignant cells remaining post[illegible] [illegible]ent work suggests, however, that this form [illegible]ent is no more effective than lavage with sterile [illegible]

The clinical aspects of mercury nephrotoxicity have been well reviewed (Schreiner and Maher, 1965; Hollenberg et al., 1970), as has the mode of action of mercury in causing acute renal failure (Oken, 1972). We have found one previous report of acute renal failure following peritoneal lavage with a 1 : 500 solution of mercuric chloride (Gingell et al., 1967).

In our cases, the acute renal failure may have been the result of absorption of toxic quantities of mercury, combined with the hypotension which resulted from the exudative peritoneal reaction in each case. An inflamed peritoneum would enhance absorption of mercury, and the hypotension would increase its nephrotoxic potential. There was no other obvious cause for the acute renal failure and the hypotension alone was not thought to be severe enough to explain it.

The onset of nephrotic syndrome in one of our cases is further supportive evidence that mercury toxicity was involved in the initial illness. No other cause for nephrotic syndrome was found. The renal biopsy changes of mercury-induced nephrotic syndrome are legion and the presence of only minor changes is quite consistent with the diagnosis.

Many patients treated with intraperitoneal mercuric chloride do not develop acute renal failure, although the recommended concentration for use on raw surfaces is lower than that used in our cases. Perhaps an intense chemical peritonitis represents an idiosyncratic reaction to the drug? However, in the absence of firm evidence that the treatment is effective, one can only echo Schreiner's words from 13 years ago: 'The use of mercuric salts for douching and surgical irrigation should be discouraged' (Schreiner and Maher, 1965).

gation: a survey of patient opinion

RRICOTT, M. R. B. KEIGHLEY, G. D. OATES
LIAMS*

SUM. [illegible]
Patients [illegible] rrigation via a naso-gastric t[illegible] by a questionnaire answered b[illegible] nts who received this method of bowel pre[illegible] before operation on the large bowel or colonoscopy. Abdominal pain during the irrigation was experienced by 13 patients (17 per cent) and nausea and vomiting occurred in 24 (30 per cent). Intubation with a nasogastric tube and the discomfort of prolonged sitting on a commode were considered the most disagreeable aspects of the procedure. Fifty-six patients (71 per cent) would have agreed to the irrigation being repeated if necessary and many patients preferred whole gut irrigation to previous 'orthodox' bowel preparations that they had experienced.

WHOLE gut irrigation as a method of washing the bowel clean has come into use in many centres since it was first described by Hewitt et al. in 1973, and the technique is now often used for bowel preparation before operation, colonoscopy and radiology. Three years ago we reported our experience in 81 patients (Crapp et al., 1975) and we have continued to use this method of preparation before colonoscopy and operation.

Although the procedure is widely used in several hospitals, some nurses and doctors consider it too distressing for the patient and others believe the technique to be dangerous. Attempts have been made to assess patient acceptance of whole gut irrigation. Levy et al. (1976) studied 21 patients prepared for barium enema examination and also for colonoscopy. For one investigation they were prepared by oral castor oil and cleansing enemas and for the other by drinking isotonic saline at the rate of 1 l/40 min. Sixteen (76 per cent) patients preferred the lavage. Hewitt et al. (1973) reported that 2 of the 6 patients who had experienced both whole gut irrigation and conventional large bowel preparation with cathartics and enemas preferred irrigation. The purpose of this paper is to report the results of a survey of our patients' acceptance of the procedure and to recommend modifications to increase acceptability.

Patients and methods

Method of irrigation

Patients were admitted to hospital on the day before operation or colonoscopy. No dietary restrictions were imposed and the procedure was explained to the patient. The subject was weighed before and after irrigation. A 'Salem' sump tube (size 14) was passed via the nose and the patient seated on a commode. Intramuscular metoclopramide (10 mg) was given before irrigation and as necessary throughout the procedure to control nausea and abdominal distension. Isotonic saline at 37 °C, without potassium supplements, was used as an irrigant. The saline was delivered by conventional gravity feed in the majority of irrigations, but this was later substituted by a Watson–Marlow Flow Inducer (MHRE 22), which gave a constant rate of infusion and was less cumbersome for the nursing staff to use. The maximum flow rate for each subject was regulated to as fast as possible without producing symptoms of nausea and abdominal distension, and varied between 2 and 4 l/h. Urine output was recorded and the procedure stopped when the anal effluent became clear. The mean time taken was 3½ h (range 2–6).

Questionnaire (Table I)

Ninety-nine patients who had received whole gut irrigation between July 1976 and December 1977 were sent questionnaires. All were questioned within 1 month of hospital discharge. Fifty-two of the patients had been prepared for colonoscopy and 47 had been prepared for an operation on the large bowel. Seventy-nine (80 per cent) questionnaires were completed and returned. The average age of the 79 patients was 53·8 years (range 17–84 years). Forty-three were male and 36 female.

Table I: REPLIES TO THE QUESTIONNAIRE ON WHOLE GUT IRRIGATION (79 PATIENTS)

	Yes	No	No answer
Part I			
1. Did you understand why this cleaning of the bowel was being performed?	77	1	1
2. Were you apprehensive or afraid?	30	47	2
3. During the procedure did you experience:			
a. Pain?	13	64	2
b. Feeling of sickness?	29	49	1
c. Vomiting?	24	54	1
d. Discomfort in the back passage?	12	66	1
e. Discomfort from sitting on the commode?	49	27	3
4. After it was finished did you feel unwell?	25	54	0
Part II			
5. Which of the following did you consider the most disagreeable:			
a. Passing of the tube into the stomach?	46		
b. Discomfort of sitting?	23		
c. Stomach pains?	1		
d. Embarrassment of the procedure?	5		
e. None?	4		
6. If it was necessary to perform the cleaning again would you—			
a. Agree without hesitation?	30		
b. Agree but worry about it?	26		
c. Consider refusing but feel it was necessary?	19		
d. Refuse?	4		

Results

The results of the questionnaire are shown in *Table I*. Although 77 of the 79 patients (97 per cent) understood why the irrigation was being performed, 30 (38 per cent) admitted to being afraid of the procedure. Forty-six (58 per cent) found the presence of a nasogastric tube the most distressing part of the method, but 23 (29 per cent) considered that the discomfort of sitting on the commode was more disagreeable. Discomfort from prolonged sitting was experienced by 49 patients (62 per cent). Nausea was

A new appliance for collecting ileostomy and jejunostomy fluid in the postoperative period

G. L. HILL AND I. R. PICKFORD*

SUMMARY

A new lightweight two-piece ileostomy appliance was tested in 11 patients with newly established ileostomies and jejunostomies. Seven of the patients presented difficult stoma care problems. The appliance was fitted in theatre on completion of the operation and the patient was followed until discharge from hospital.

The appliance remained in place for an average of 4·8 ± 1·2 days. In a total of 204 patient-days the pouch became dislodged from the flange on 10 occasions and there was leakage under the body flange on 7 occasions. All but one of the patients continued to use the appliance on discharge. No patient was allergic to the appliance nor complained of odour.

It is concluded that this new appliance represents an important advance in postoperative stoma care.

WITH the widespread use of the eversion type of ileostomy and immediate mucocutaneous suture it has become the custom to apply an adherent ileostomy appliance in theatre, as soon as the ileostomy has been established. The ideal appliance for this purpose needs to be leakproof and odourproof, lightweight and able to be easily adapted for final use. It should also be in two pieces, so that the bag can be removed to allow easy access to the stoma without having to separate and reapply the adherent flange.

In this paper we describe our experience with a new ileostomy appliance which fulfils many of these criteria. We have used it in a group of particularly difficult patients with newly established ileostomies and jejunostomies.

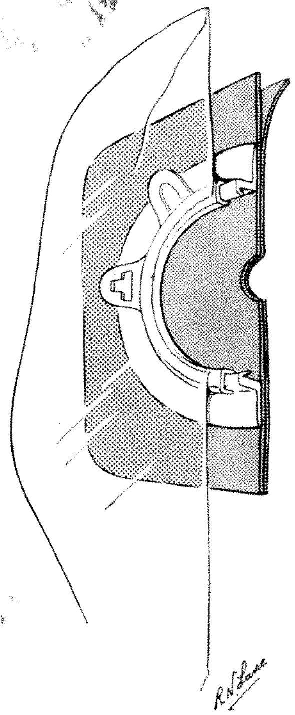

Fig. 1. The appliance consists of a transparent plastic pouch connected to a body flange via a snap lock.

Patients and methods

The appliance

The two-piece appliance (Surgicare System 2, Squibb & Sons Ltd) is based on the skin barrier Stomahesive, a preparation of pectin and methylcellulose (gelatin 20 per cent, pectin 20 per cent, sodium carboxymethylcellulose 20 per cent, polyisobutylene 40 per cent). It consists of a body flange and drainable bag (*Fig.* 1). The body flange is a 4-in (approx. 100-mm) square of Stomahesive attached by means of a double-sided adhesive disc to a low density polethylene injection-moulded flange. The transparent drainable bag is made of a trilaminate plastic sheeting 75 μm thick. Welded to the bag, around the point of stoma entry, is an ethylene vinyl acetate flange, which is the corresponding component to the flange attached to the Stomahesive square. The two flanges seal together via an ingenious type of snap lock (*Fig.* 2). The end of the drainable bag is sealed with a polypropylene clip.

Fitting of the appliance

The flange unit is applied to the new stoma as soon as the mucocutaneous sutures have been inserted and the surrounding skin has been prepared. The skin is cleansed with cetrimide and carefully dried before being thoroughly de-greased with ether. Attention is then turned to preparing the flange unit for application. When selecting the correct flange size it must be remembered that swelling of the stoma can occur and it is important that the diameter of the opening in the face plate allows at least 0·5 cm for expansion. In most patients a flange with an internal diameter of 45 mm (1¾ in) can be used but other diameters (28 mm, 57 mm and 70 mm) are available.

The centre hole in the Stomahesive flange unit is not enlarged directly. If radial slits are made (*Fig.* 3) and the opening is gently shaped with the fingers so that it will fit snugly over the stoma (*Fig.* 4) a very adequate watertight seal can be obtained. The silicone release paper covering the skin side of the Stomahesive is then removed and the whole flange unit is positioned over the stoma and pressed firmly on to the skin (*Fig.* 5). If the surgeon has removed his gloves before this manoeuvre the warmth from his hands aids adherence of the Stomahasive to the skin. It is advisable to take a little time holding the flange in this way, because it will then mould to the contours of the skin and prevent channelling of small bowel fluid. Care is taken to ensure that the seal around the circumference of the stoma is also complete. The pouch is then attached to the flange unit via the snap lock, remembering to position the outlet in the flank so that drainage will be facilitated while the patient is lying in bed (*Fig.* 6).

Patients

We have used the new appliance on 11 patients in whom we have recently performed an end ileostomy or jejunostomy. Although 4 of these patients had well-made, normally functioning ileostomies the others had stomas that were far from ideal (*Table I*). Among these were 3 patients with jejunostomies and

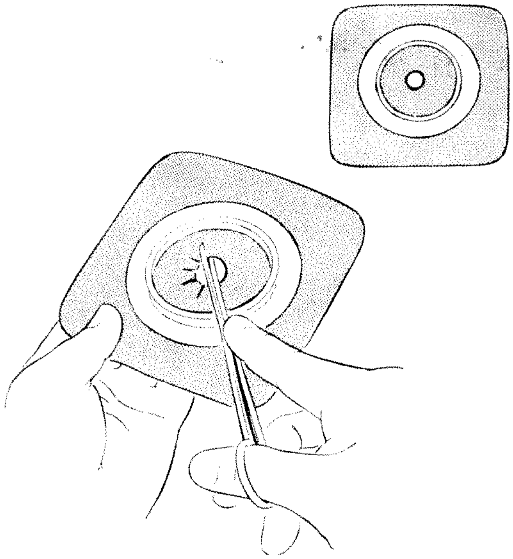

Fig. 3. Preparing the body flange: radial slits are made in the Stomahesive.

each of these had flush stomas with daily faecal outputs of 1–3 l. There was also a male patient (*Case* 5) who had a particularly difficult stoma which was large, swollen and oedematous and passed profuse amounts of loose ileostomy fluid.

Results

Acceptability

In all but one of the patients, *Case* 5, the appliance proved to be comfortable and no patient was sensitive

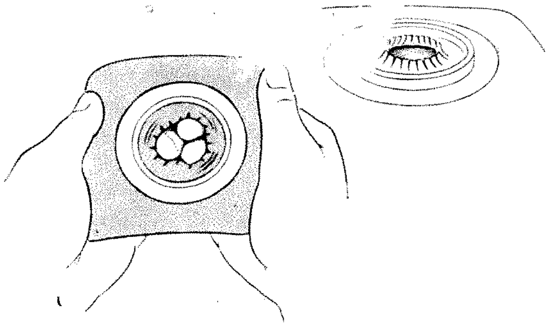

Fig. 4. Preparing the body flange: the opening is shaped to accommodate the stoma.

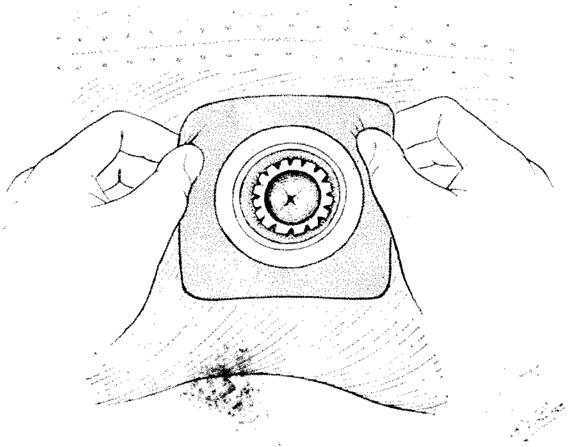

Fig. 5. The body flange is sited over the stoma and the Stomahesive is held on to the skin aiding adhesion with the warmth of the hands.

Table I: DETA[illegible] OF [illegible]ATIENT SERIES

Case	Age (yr)	Sex	Type of stoma	Stoma problem	Size of appliance used (mm)	Days in hospital after surgery	Total no. of appliances used	Complications		Final outcome
								D	L	
1	51	F	Ileostomy: output 0·5 l/d	Obese patient, flush stoma	45	28	5	1	0	Home with appliance
2	60	F	Ileostomy: output 0·5 l/d	Obese patient, normal stoma	45	8	2	1	0	Home with appliance
3	40	F	Jejunostomy: output 2–3 l/d	Flush stoma	45	12	3	1	2	Home with appliance
4	48	F	Ileostomy: output 1–2 l/d	Normal stoma	45	7	2	1	0	Home with appliance
5	56	M	Ileostomy: output 1–1·5 l/d	Large swollen stoma	75	8	3	3	0	Changed to another two-piece appliance
6	52	F	Ileostomy: output ≃ l/d	Moderately obese, very short stoma	45	28	6	1	0	Home with appliance
7	40	F	Jejunostomy: output 2–3 l/d	Flush stoma	45	28	6	0	3	Home with appliance
8	47	F	Ileostomy: output 0·5–1 l/d	Flush stoma	45	35	6	2	1	Home with appliance
9	31	M	Ileostomy: output ≃ 1 l/d	Normal stoma	45	31	5	0	1	Home with appliance
10	71	M	Ileostomy: output 1–2 l/d	Normal stoma	45	7	1	0	0	Home with appliance
11	39	F	Jejunostomy: output 1–1·5 l/d	Flush stoma	45	12	3	0	0	Patient still in hospital using the appliance

D, displacement; L, leakage.

to the Stomahesive body flange. With practice the nurses were able to secure the snap lock with sufficient gentleness to avoid undue pain. During the recuperative phase all the patients quickly learned how to manage the appliance and the ease of the snap lock system proved to be a real help when excessive gas had to be released. Offensive odour was never complained of and the medical and nursing staff generally felt that the appliance was odour-free.

Ten of the patients are now home and all but one are continuing to use the appliance (*Table I*). Each claims to be satisfied with it. *Case* 5, who had a large and swollen stoma, was never happy with the appliance, which had become dislodged on three occasions during his hospital stay, and he now uses a two-piece appliance consisting of a large rubber flange and a black rubber drainable bag.

Complications

Over the entire study period the body flange remained in place for an average of 4·8 ± 1·2 days (range 2–7 days). In 7 patients the bag became disconnected from the body flange on at least one occasion (10 times in 204 patient-days). In each case the bag had become overfull and a sudden movement by the patient had pulled the snap lock apart. In 4 patients leakage occurred when the body flange lifted from the skin. Three of these patients had stomas that were flush with the skin and leakage had occurred under the body flange in the region of the mucocutaneous junction. *Case* 7, 4 weeks after the establishment of a flush jejunostomy, now finds it necessary to change the whole appliance every 1 or 2 days because of skin irritation consequent upon leakage under the Stomahesive barrier. No other patient has severe peristomal skin soreness. On three occasions, when a patient had been moving about with the pouch full of fluid, the Stomahesive split near the circumference of the polyethylene flange. This quickly resulted in leakage and a new body flange was required.

Discussion

Although the patient is usually very ill and passive after ileostomy surgery important long term attitudes are developed during the postoperative period. Experiences with the stoma at this early stage have an important influence upon the patient's subsequent recovery and rehabilitation. Clearly it is of crucial importance that the patient sees that the stoma works well. Leakage, skin irritation and nauseating odour raise fears and increase doubts in the patient's mind as to his ability to cope with this new situation. Thus, any new appliance which functions well in the postoperative period and is free from troubles such as leakage, skin irritation and odour is an important advance in this difficult branch of surgery. Although it is not perfect, the results show that this new appliance, used here on a particularly difficult group of patients, has worked well. All the patients have found it to be light and simple to use.

Before the appliance can be confidently recommended for long term use, however, a more formal trial, in a wide variety of patients, is required. On the other hand, we have little hesitation in recommending its use in the recovery phase after stoma surgery.

The Stomahesive body flange, as might be expected, proved very satisfactory. On only 7 occasions in more than 200 days did leakage occur under the flange. Since the first full length trial of Stomahesive (Kyte and Hughes, 1970), there has been a growing awareness that it is one of the best available barriers against corrosive small bowel contents. A recent study (Marks, 1978) showed that Stomahesive produced the lowest degree of skin irritation when compared with several other widely used adhesives. Until recently it has been used in enterostomal therapy as an adhesive skin barrier under a variety of face plates and adhesive pouches. Although such arrangements have proved very helpful in some patients, they are rather cumbersome and somewhat complicated to use. Clearly, this new two-piece appliance, in which a light plastic pouch is simply snapped on to a square of [illegible] is an important advance.

One of the crucial parts of the [illegible] lock which connects the pouch to the [illegible] spite of our initial doubts, the snap lock [illegible] generally functioned well. Our study has shown, however, that it is not perfect, for when the pouch becomes overfull and heavy, vigorous movement can dislodge it. This problem is infrequent (10 times in 204 days) and can be avoided in most instances, although it is extremely distressing for the patient when it occurs. On the other hand, the snap lock has major advantages. The knack of fastening the lock is quickly acquired and it is most helpful to be able to remove the pouch to examine the stoma or release excessive gas.

Of major importance to the convalescent patient is the gas transmission qualities of the pouch material. New generation plastics and plastic laminates are becoming increasingly popular as pouch materials [illegible] from this [illegible].

In conclusion, we feel that this is the best [illegible] appliance we have used for the postoperative care of small bowel stomas. It is not yet the last word, but it works well and is worth the attention of all surgeons who perform this type of surgery.

acute urinary

SALEM AND IAN RAMSAY*

SUMMARY

Three elderly patients presented at one hospital in a 2-week period with acute urinary retention precipitated by the hyperosmolar non-ketotic diabetic state. In each case routine urine testing was reported as showing 1 per cent glycosuria. The first two patients were admitted at night and blood glucose estimations were not done. This led to a delay of 16 and 12 h respectively before the appropriate therapy was instituted. It is suggested that this clinical presentation, previously unreported, may not be a rarity and represents an avoidable cause of death in patients with acute urinary retention.

THE hyperosmolar non-ketotic diabetic state (HNKDS), with or without coma, usually occurs in elderly diabetics, often with previously unrecognized disease. Subclinical prostatism is common in this age group. Surprisingly, acute urinary retention as the presenting feature of the diabetic hyperosmolar state has not been reported in the literature before. We would like to report 3 patients, subsequently diagnosed as having HNKDS, who were all admitted to one hospital within a period of 2 weeks because of acute urinary retention.

Case reports

Case 1: A 69-year-old man, not previously known to be diabetic, was admitted to the surgery department at 1.00 a.m. with acute urinary retention. He had last passed urine 26 h before admission. He gave a history of thirst and polyuria for 3 weeks and of stress incontinence for 1 week. There was no other previous history of urinary symptoms. He had taken no drugs apart from dextropropoxyphene (Distalgesic) for his cervical spondylosis.

On examination he was found to be dehydrated. His drowsiness was attributed to his urological condition. His bladder was palpable up to the umbilicus and rectal examination revealed an enlarged, smooth prostate. No obvious neurological abnormality was found. Catheterization yielded 2000 ml of urine which was said to contain 1 per cent glucose and 1+ of albumin. The initial urea and electrolyte estimations are shown in *Table I.* He was treated with dextrose saline infusion, 500 ml every 4 h with 1 g of potassium in alternate bottles. Fluid balance charts showed that a polyuria of 4000 ml/6 h was occurring. Urine testing with Multistix (Ames Ltd) continued to be reported as showing 1 per cent glycosuria. However, his condition was deteriorating; 16 h after admission his blood glucose was 45 mmol/l and he was referred to the physicians. The further investigations are shown in *Table I.* He was given 30 units of soluble insulin intravenously and 30 units intramuscularly and received 4 l of half-strength normal saline with supplementary potassium. Four hours later he was given a further 80 units of insulin intravenously. Despite a falling blood glucose his condition continued to deteriorate and he died 24 h after admission.

Case 2: An 83-year-old man, not known to be diabetic, was admitted to the surgery department at 1.00 a.m. with acute urinary retention. He was drowsy, confused and dehydrated. Subsequently he was able to give a history of thirst and weight loss for 6 months, polyuria for several weeks and retention of urine for approximately 12 h. He had not received any drugs. There was no history of hesitancy or terminal dribbling. The bladder was palpable up to just below the umbilicus. The prostate did not feel enlarged on rectal examination and only soft faeces were present. Neurological examination revealed no abnormality. Catheterization obtained 1200 ml of urine and Multistix examination was reported as showing 1 per cent glucose. The initial urea and electrolytes are shown in *Table I.*

Twelve hours later the patient was more confused and unwell. He had pulled his catheter out and the bladder was once again palpable. A blood glucose estimation was done and found to be 52 mmol/l; the patient was then referred to the physicians. He was treated with half-strength normal saline, insulin and heparin. Within 9 h his blood glucose had fallen to 8·3 mmol/l and 2 days later he had fully recovered and was up and about. A CSU was sterile and no abnormality was found on microscopy. Subsequently he had no significant urinary obstructive symptoms but an intravenous pyelogram did show a trabeculated bladder and a small residual volume after micturition. His diabetes was well controlled on diet and glibenclamide 5 mg per day.

Case 3: A 76-year-old male Cypriot diabetic, treated by diet alone, was referred to the surgical department with acute urinary retention at 11.00 a.m. He was distressed and dehydrated, could not speak English, but pointed to his lower abdomen. His bladder was palpable up to his umbilicus and his prostate was slightly enlarged. Neurological examination was normal apart from absent ankle jerks. Catheterization yielded 1500 ml of urine. Testing with Multistix was reported as showing 1 per cent glucose. Because of the experience with the previous two patients he was referred to the physicians. Blood glucose and electrolyte estimations confirmed the diagnosis of a hyperosmolar diabetic state. The initial investigations are summarized in *Table I.*

He was treated with half-strength normal saline, heparin and both intravenous and intramuscular soluble insulin. At 24 h after admission his blood glucose was 7·8 mmol/l and he was feeling generally quite well apart from some breathlessness. A CSU showed no microscopic abnormality and was sterile on culture.

Through an interpreter he gave a history of chronic bronchitis for many years. He had been unwell for 1 week before admission, with thirst and polyuria, but until he developed urinary retention had not had any obstructive symptoms. He had not been on any drugs. His ECG showed ventricular ectopic beats and some ischaemic changes. Four days after admission he went into acute left ventricular failure which did not respond to treatment and he died.

Discussion

The hyperosmolar diabetic state is associated with massive diuresis secondary to severe hyperglycaemia; this results in marked dehydration, haemoconcentration and hyperosmolality. At the time of presentation most patients are either in pre-coma or coma (Halmos et al., 1966). Although subclinical benign prostatic hypertrophy occurs in 73 per cent of men above the age of 60 (Franks, 1954), it is surprising that acute urinary retention has never been reported as the initial presentation of the hyperosmolar non-kinetic diabetic state (HNKDS).

Acute urinary retention is usually considered a surgical emergency and patients with HNKDS presenting in this way would thus be admitted under the surgeons. This happened in all three of our patients

and resulted in a delay of 16 and 12 h respectively in the first two patients before the start of appropriate treatment. As in all acute diabetic metabolic disturbances, the earlier the treatment the better the prognosis (Arieff and Carroll, 1972) and this is especially true for the hyperosmolar diabetic state, which usually occurs in elderly patients and is associated with a high mortality rate (Danowski and Nabarro, 1965; Field, 1976). The first patient died in the acute phase of hyperosmolality; permission for post-mortem examination could not be obtained. The third patient died from intractable left ventricular failure 4 days after admission following full correction of the hyperosmolar state. The second patient is alive and well 14 months after his original admission. None of the factors known to precipitate HNKDS, such as diuretic therapy (Field, 1976), was present in our patients.

In any patient with acute urinary retention an underlying precipitating factor should always be sought. None of our patients had obvious evidence of diabetic neuropathy. Urine testing with Multistix was clearly a factor contributing to the delay of treatment in the first two patients. In each case the result was recorded as 1 per cent, and this was not thought by the surgeons to warrant an emergency blood-glucose estimation during the night. In fact it can be difficult to differentiate between a glycosuria of 1 per cent and 2 per cent or more using Multistix. A more easily quantifiable method of estimating glycosuria such as Clinitest (Ames Ltd) would have probably alerted the admitting doctor to the serious nature of the patients' condition and would have led to more prompt investigation and treatment.

We suggest that any degree of glycosuria in an elderly patient with acute urinary retention should be immediately checked by a blood-glucose estimation. Urea, electrolytes and osmolality should also be measured as, occasionally, considerable hyperosmolality can occur in the face of moderate hyperglycaemia (Jarrett and Bacon, 1963; Danowski and Nabarro, 1965). The fact that we saw three patients with HNKDS presenting at one hospital with acute urinary retention during a 2-week period may indicate that the condition has been previously overlooked.

Cytological study of fluid from breast cysts

P. N. COWEN AND E. A. BENSON*

SUMMARY

A series of 215 patients with breast cysts has provided 348 specimens of cyst fluid for cytological diagnosis. Only one of these specimens was reported positive for malignant cells and this patient had a carcinoma. Nine specimens were reported as suspicious, but none of these patients had or subsequently developed carcinoma. In 338 specimens cytology was negative. A total of 178 patients (294 specimens) was available for follow-up. Of these 2 proved to have carcinomas on immediate follow-up, i.e. a lump persisted after aspiration, and a further 2 patients developed cancers in the same breast, one 4 and the other 7 years after aspiration. We therefore conclude that the routine submission of breast cyst fluid for cytology is wasteful of time and resources.

We do not propose to discuss the merit of needle aspiration in the management of breast cysts. Controversy has existed in the past as to whether excision biopsy is a safer procedure (Atkins, 1952; Keynes, 1966). We believe, however, that aspiration is now a generally acceptable procedure, and are supported in this view by Patey and Nurick (1953), Schnug and Cavanagh (1966), Forrest (1974), Rimsten et al. (1975) and Rosemond et al. (1977).

We propose to confine ourselves to investigating the value of the routine cytological examination of fluid removed from breast cysts, since it appears that there is a difference of opinion as to its value. Patey and Nurick (1953) appear to have been the first to suggest the importance of cytology in reducing the risk of missing a breast carcinoma (although these authors also stated, somewhat paradoxically, that there was no clear relationship between fibrocystic disease and breast cancer). Their view is supported by Forrest (1974) and Rimsten et al. (1975). Equally, Schnug and Cavanagh (1966) and Rosemond et al. (1977) are of the opinion that cytological examination of cyst fluid is unnecessary.

It appears that the type of carcinoma which may be present can have a bearing on the usefulness of cytological examination and there are two situations to consider. First, in the case of true intracyst carcinoma (*Fig.* 1*a*), cyst fluid cytology could conceivably be valuable; however, the incidence of this particular type of growth is extremely low. Gatchell et al. (1958) quote an incidence of only 0·5 per cent, Kalisher (1977) states that it is 'a rare entity' and Rosemond et al. (1977) quote an incidence of 0·1 per cent. This conclusion has been borne out by our experience in this teaching hospital pathology department, where carcinomas are rarely seen in association with cysts and where intracystic carcinoma is virtually non-existent. If, therefore, we aim to avoid missing these extremely rare tumours by using cytological examination, we shall be assessing a large number of samples totally unnecessarily. If we consider the second situation, the coincidental occurrence of a carcinoma side by side with cysts in the same breast (again, in our experience, an uncommon, though perhaps not rare, situation) (*Fig.* 1*b*), routine examination of cyst fluid is not likely to help in this case as the growth is at some distance from the cyst and cannot be expected to exfoliate cells into the cyst fluid. It should be noted, however, that decompression of the cyst may well make the carcinoma easier to feel clinically.

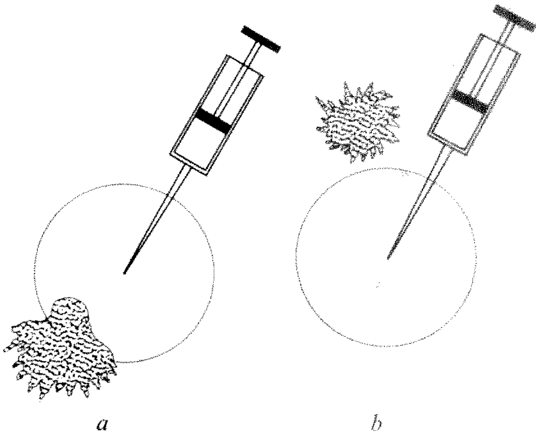

Fig. 1. (*a*) A true cystic carcinoma; (*b*) carcinoma coincidental with a breast cyst.

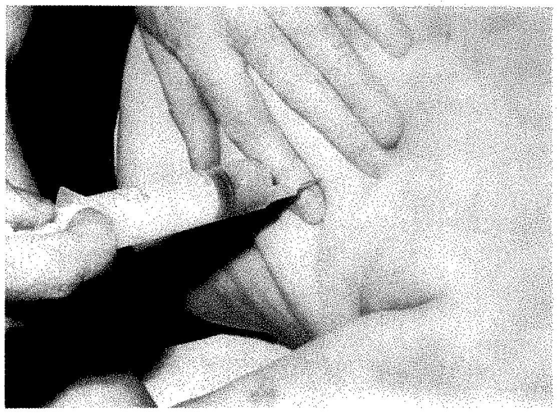

Fig. 2. Needle aspiration of a breast cyst.

Having analysed the problem in this way it appeared to us, on theoretical grounds at least, that it was highly improbable that routine cytology of aspirates from breast cysts was likely to be of any significant value whatsoever as regards detecting an occult carcinoma, and we felt impelled to re-examine the logic of this exercise. We were influenced in this by a retrospective study by one of us (P. N. C.), who had reviewed 106 specimens from 83 patients with breast cysts collected between 1964 and 1970. No malignant cells were found in any of these specimens and of the 67 patients who could be followed up, none subsequently developed breast cancer.

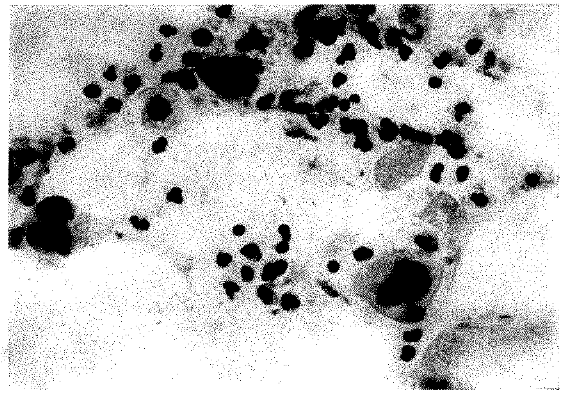

Fig. 4. Large, bizarre cells from squamous carcinoma with pus cells. (HE. ×390.)

Patients and methods

A prospective study was undertaken from November 1970 to December 1976. Patients were attending the surgical out-patients' clinic at the General Infirmary at Leeds and the majority were attending one unit, i.e. the Combined Breast Clinic. Patients whose lesions were diagnosed as breast cysts were treated by needle aspiration, without local anaesthetic (*Fig.* 2). Each cyst was aspirated as completely as possible and the fluid sent in a clean, dry, sterile bottle to the pathology department where it was received within 2 h. The fluid was then centrifuged for 5 min at 1500 rev/min (MSE Super Minor Centrifuge), the supernatant was pipetted off and the sediment then smeared on to a slide which was fixed in 50/50 ether alcohol or pure absolute alcohol. The slide (which was never allowed to become dry) was then stained with haematoxylin and eosin and the smear mounted with a cover slip as for conventional histology. Typical smears of breast cyst contents are seen in *Fig.* 3.

Results

In general, a few cells were found in the cyst smears. Most were recognized as epithelial cells or histiocytes and occasionally numerous pus cells were present. The results are shown in *Table I*. Three hundred and forty-eight specimens were obtained from 215 patients (some being repeat aspirations in the same patient) and in 1 case positive cytology was obtained (*Fig.* 4), though there were 9 'suspicious' reports. Three hundred and thirty-eight specimens contained either benign or no cells. The single patient with positive cytology did indeed have a breast carcinoma, though this was not intracystic but a squamous carcinoma that had become necrotic centrally.

Table I: SUMMARY OF NUMBERS OF PATIENTS AND SPECIMENS IN THE SURVEY TOGETHER WITH THEIR CYTOLOGY REPORTS AND THE RESULTS OF FOLLOW-UP

	No. of patients	No of specimens	Report		
			+ve	Suspect	−ve
Totals	215	348	1	9	338
Cases lost to follow-up	37	54	0	1	53
Cases followed up	178	294	1*	8†	285‡

Result of follow-up: * Positive confirmed. † None had or developed a new growth. ‡ Four had or developed breast cancer.

Although we had failed to detect cancer at initial presentation in the vast majority of these women it was just conceivable that a neoplastic lesion might have been missed, and for this reason as many of these patients as possible were followed up. Thirty-seven patients were lost to follow-up, leaving a total of 178 for study over a period of up to 7 years. Eight of the 9 suspicious cases were followed and none developed a carcinoma, 5 of these also have negative biopsies. The 1 suspicious case was lost to follow-up but we have no reason to believe (because of referral patterns in Leeds) that this patient developed a carcinoma. Four patients with negative cytology, however, were subsequently proved to have breast carcinoma. In 2 of these cases, on immediate follow-up a lump persisted after aspiration and in both cases a carcinoma was found at the site of the lump, i.e. their carcinomas had been clinically unmasked by decompression of coexisting breast cysts. In the other 2 cases the patients developed a carcinoma in the same breast as the cyst, one at 4 and the other at 7 years after aspiration. In our opinion these cases could hardly be considered false negatives.

Discussion

Once a cytology service is established surgeons will tend to send samples to it without necessarily critically examining its usefulness. However, Forrest et al.

(1975), are of the opinion that breast cyst cytology is useful, since out of 149 cysts aspirated by them, abnormal findings in 36 patients led to excision of the cyst, revealing carcinoma in 4 cases. This yield was significantly higher than ours. Others have also reported a higher incidence of cancer associated with cysts than we experienced; Patey and Nurick (1953) found 8 carcinomas associated with 76 cysts and Rosemond et al. (1955) reported 2 carcinomas associated with 140 cysts. As we have indicated previously, intracystic carcinoma is in itself extremely rare and it seems a futile exercise to hope to recognize such growths by routine cytology. Furthermore, since there is no definite relationship between fibrocystic disease and breast cancer, needle aspiration of cysts in fibrocystic disease is not likely to be particularly rewarding. Gaspar (1961) reviewed 15 surveys of breast cyst aspiration studies, including his own, and his conclusion was that 'As Papanicolaou examination of breast cyst fluid is unrewarding, this procedure has been abandoned.' His review included a total of 1364 patients with breast cysts, 12 of whom had cancers. In 4 cases these carcinomas were associated with cysts, in a further 4 patients these occurred in the same breast but not in the cyst and in the remaining 4 they occurred in the contralateral breast. Small surveys are reported by Roth et al. (1977) and Van Bogaert and Mazy (1977) in which 72 cysts were aspirated and all were negative cytologically. A recent large survey is that of Rosemond et al. (1977), who had only 3 cancers in 3000 cyst aspirates and therefore concluded that cytology is unnecessary.

From our own experience, we have confirmed that needle aspiration of breast cysts is a safe and reliable method of treatment. We conclude that there is nothing to be gained by routinely submitting breast cyst fluid for cytology, since the risk of missing a carcinoma is very small, particularly if the following clinical protocol is obeyed: Recommend biopsy if (*a*) *aspiration fails*, i.e. the lump may be solid, or (*b*) the lump recurs after *re-examination at 1 month*, if mammograms indicate the necessity. Routine cytology is therefore not only unnecessary but wasteful of time and resources. In this series we were interested to note that 4 of the 178 patients with negative cytology either had (2 cases) or subsequently developed (2 cases) a carcinoma. This does not appear to indicate an appreciable risk for patients with fibrocystic disease and we believe that this is generally the experience of others.

Finally, we would reiterate the general clinical rules for follow-up in patients in whom cysts are aspirated. It is most important after aspiration of a cyst that careful re-examination of the breast at the time and again 4 weeks later is carried out. Should a lump persist or recur we believe that mammography is indicated and a decision is then taken as to whether repeat aspiration or excision biopsy should be undertaken.

Spontaneous rupture of a liver cell adenoma after long term methyltestosterone: report of a case successfully treated by emergency right hepatic lobectomy

DAVID BIRD, KEITH VOWLES AND P. P. ANTHONY*

SUMMARY

A case of spontaneous rupture of a liver cell adenoma is reported in a female transexual treated with methyltestosterone 150 mg daily for 7 years. Emergency right hepatic lobectomy was performed successfully. Histology showed peliosis hepatis also.

Emergency resection of a liver cell adenoma has been reported in a young woman taking oral contraceptives, and an elective resection in another female transexual treated with methyltestosterone. However, to the best of our knowledge this is the first case of emergency resection of a spontaneously ruptured liver cell adenoma in a transexual treated with long term methyltestosterone. Since there are numerous other patients similarly treated, it may be expected that this complication will be seen again.

Case report

A 39-year-old female-to-male transexual was admitted as a surgical emergency. He had been treated with methyltestosterone 150 mg daily for the past 7 years, and had undergone bilateral subcutaneous mastectomy, hysterectomy and bilateral salpingo-oophorectomy. He had previously borne a child. Whilst on holiday he experienced a gradual onset of constant abdominal pain, which after 48 h became severe and radiated to the right scapular region. On examination he was well built, tanned, muscular, bearded, with profuse body hair of male distribution, but had female genitalia and an enlarged clitoris. He was febrile (38 °C) and in pain, with a sinus tachycardia of 115/min. The abdomen was slightly distended, with generalized tenderness and guarding, most marked in the right upper quadrant. The upper abdomen was dull to percussion, filled by an ill-defined mass, but the liver and spleen were not palpable. Bowel sounds were present and rectal examination was normal.

Investigations showed Hb 7·4 g/dl, WBC 27·6 × 10^9/l, blood urea 19·7 mmol/l, bilirubin 39 mmol/l, alkaline phosphatase 213 mU/ml, LDH greater than 608 mU/ml, SGOT greater than 253 mU/ml and amylase 255 U/l. Abdominal X-rays showed an opaque mass filling the entire right upper quadrant.

Laparotomy revealed a copious stale haemoperitoneum for which initially no cause could be found, but eventually a ragged split some 15 × 10 cm was felt in the most posterior part of the dome of the *right* hepatic lobe, which was greatly enlarged and softened and appeared to contain a large, friable, pale-red mass. The spleen was of normal size, and there was no evidence of portal hypertension.

The incision was extended into the right chest, and as it seemed that the bleeding could be controlled in no other way, a right hepatic lobectomy was performed. The common bile duct was not drained, several large peritoneal drains were inserted and broad spectrum antibiotics, 10 per cent dextrose and salt-poor albumin were given for several days. Postoperative recovery was uneventful, and the serum glucose and albumin, platelet counts and clotting profiles all remained within the normal ranges.

Pathological examination of the resected lobe revealed an ill-defined mass occupying most of the resected lobe. The mass was haemorrhagic and slightly paler than normal liver, but not clearly demarcated from it. Histologically the tumour was a liver cell adenoma composed of normal-looking liver cells arranged in irregular plates and separated by sinusoids. Portal tracts were absent. The appearances were id[illegible] those reported by Paradinas et al. (1977). In ad[illegible]ous thickened blood vessels were present, and the [illegible] many areas of necrosis and haemorrhage, the latter filling cavities not lined by epithelium. The histological appearances were those of peliosis hepatis and liver cell adenoma.

Discussion

17-Alpha-alkylated androgenic–anabolic steroids such as methyltestosterone may cause abnormalities of the standard liver function tests, which revert to normal if the drug is stopped (Foss and Simpson, 1959). Carbone et al. (1959) studied 17 patients with normal liver function given methyltestosterone 67 mg per day. At the end of 3 weeks 40 per cent showed elevation of plasma SGOT and 90 per cent showed BSP retention greater than 6 per cent 45 min after injection.

Methyltestosterone and oxymetholone may cause cholestatic jaundice, but this is an unusual complication (Wynn et al., 1961). Although 60 per cent of patients showed elevated SGOT after a 3–5-week course of norethandrolone (60 mg daily), needle biopsy revealed cholestasis in only 15 per cent (Schaffner et al., 1959).

17-Alpha-alkylated steroids have been implicated in the development of liver tumours—which have been variously described as hepatic adenoma (Recant and Lacy, 1965; Bruguera, 1975; Westaby et al., 1977), or hepatocellular carcinoma (Dosik et al., 1970; Bernstein et al., 1971; Johnson et al., 1972)—since they have been used in all the well-documented cases. This group includes oxymetholone and methyltestosterone. It is uncertain if any of these tumours were truly malignant in that neither alpha-fetoprotein production nor metastasis was documented satisfactorily (Anthony, 1975). Paradinas et al. (1977) have decribed the morphological changes in detail, and suggested that a single pathological process (hyperplasia, related perhaps to the anabolic effects of methyltestosterone) could be responsible for both peliosis, through mechanical obstruction of hepatic veins, and the formation of nodules and tumours.

Peliosis hepatis is a benign condition of the liver of unknown aetiology, characterized by a diffuse angiomatoid change, with minute spaces of haemorrhagic appearance (Yanoff and Rawson, 1964). Peliosis hepatis has been reported after the use of norethandrolone, oxymetholone and methyltestosterone (Gordon et al., 1960; Bernstein et al., 1971; Westaby et al., 1977). In 1974 Bagheri and Boyer described 7 cases of peliosis hepatis in patients treated with anabolic–androgenic steroids. Two developed intraperitoneal

haemorrhage and died. At autopsy in each case rupture of the *diaphragmatic* surface of the *right* lobe of the liver was found. In both cases, therefore, the site of rupture was the same as in our case, in a surgically 'difficult' place.

The connection between oral contraceptives and hepatic tumours, first reported by Baum et al. (1973), has been recently discussed by Vana et al. (1977). Of 543 liver tumours of all types in the USA, 96 were liver cell adenomas. In 11 of these (11·5 per cent), intraperitoneal haemorrhage occurred, and 8 of these 11 patients died (73 per cent). When a liver cell adenoma ruptures and presents with haemoperitoneum, the mort[illegible] has been quoted as 60 per cent (Davis et a[illegible] We have found no report in the world literature of emergency hepatic resection performed for spontaneous rupture of the liver after long term methyltestosterone. Elective right hemihepatectomy for a large liver cell adenoma after the use of long term methyltestosterone has been reported by Westaby et al. (1977), and emergency extended right lobectomy for haemorrhage from an adenoma in a young woman taking oral contraceptives was described by Bein and Goldsmith (1977).

Our patient is one of the series of 60 patients treated with long term methyltestosterone 150 mg daily by Westaby et al. (1977). Eighteen were impotent males and 42 were female transexuals. Since treatment in transexuals must be life-long, further cases such as ours may be expected. It is to be hoped that virilizing drugs other than 17-alpha-alkylated steroids can be used.

Haematogenous osteomyelitis of the metatarsal sesamoid

I. J. CARTLIDGE AND W. J. GILLESPIE*

SUMMARY

A case of haematogenous osteomyelitis of the medial first metatarsal sesamoid is presented and the differential diagnosis discussed. Review of the literature suggests that the condition is rarely seen and tends to present in childhood and adolescence. This contrasts with metatarsal sesamoid osteomyelitis due to direct spread of infection, which occurs in the elderly as an important complication of the diabetic foot.

HAEMATOGENOUS osteomyelitis of the first metatarsal sesamoids was authoritatively reported for the first time by Bennet in 1935, although Lange's case (1928) of 'typical sesamoiditis' progressed to suppuration and sequestration and was probably osteomyelitis.

Smith (1941) contributed the first case in the British literature, since which time a further 6 patients with haematogenous staphylococcal osteomyelitis of the sesamoid have been recorded (Rowe, 1963; Colwill, 1969; Torgerson and Hammond, 1969).

The 2 patients described by Gordon et al. (1974) with *Pseudomonas aeruginosa* as the infecting organism had sesamoid osteomyelitis due to direct spread from a penetrating wound, while the second of the 2 cases reported by Torgerson and Hammond (1969) was that of a diabetic with deep spread of infection from an ulcerated plantar callus in a neuropathic foot.

Such cases are not rare. Over a period of 2 years until September 1977, 14 patients were seen in the Diabetic Outpatient Department at the Royal Infirmary, Edinburgh, with significant skin breakdown in the plantar aspect of the first metatarsal head. Of these, there were 3 definite cases of sesamoid osteomyelitis confirmed by radiography, and 2 others, in whom amputation had been performed for irreversible ischaemia, where preoperative radiographs suggested infective resorption of the sesamoids in addition to the adjacent first metatarsal head (Paterson, 1977).

The comparative rarity of the haematogenous variety of sesamoid infection prompts the following report of the only recorded case in the Edinburgh Orthopaedic Unit over the past 5 years.

Case report

P. F., a 15-year-old schoolboy, presented to the Orthopaedic Unit on 9 November 1976 with a 1-month history of intermittent throbbing pain and swelling on the medial and plantar aspects of the first left metatarsal head, only transiently helped by prescriptions of erythromycin and of aspirin. Up until the onset of the pain, he had been active in rugby union football, but could describe no specific precipitating trauma.

At the time of presentation, he had great pain on weight bearing, with tenderness, marked erythema and swelling on the medial aspect of the foot, associated with an area of blistering on the plantar aspect of the first metatarsophalangeal joint. He was afebrile and free of lymphangitis or lymphadenopathy, but the white cell count was 9·3 × 10^9/l with a neutrophil leucocytosis, and ESR was raised at 51 mm in the first hour (Westergren). Plasma glucose was normal, titres against staphylococci and streptococci were not raised, and no agglutinating antibodies to brucella or salmonella strains were detected. Radiographic evidence [illegible] nsidered at the time to show some rarefaction of the base [illegible] the proximal phalanx of the great toe, in comparison with a film availa[illegible] month previously at the onset of symptoms (*Fig.* 1).

No other abnormality was det[illegible] the medial sesamoid was bipartite, and, in retrospect, it is clear that the degree of separation of the parts of the sesamoid had increased in the month preceding orthopaedic presentation. Aspiration of the infected area produced no pus, but two drops of sanguinous fluid were cultured and grew coagulase-positive *Staphylococcus aureus*. A diagnosis of osteomyelitis, either in the proximal phalanx or in the metatarsal head, having been made, the left foot was kept in a plaster slipper for 2 weeks, and flucloxicillin given for 8 weeks, with resolution of physical signs and only very minor residual discomfort on weight bearing.

Radiographs taken on 29 November 1976 (*Fig.* 2) and 17 January 1977 (*Fig.* 3), however, showed increasing fragmentation of the distal component of the bipartite medial sesamoid, with migration away from the proximal component. These features were initially unrecognized. By 28 February 1977 a sinus had developed, opening on the medial aspect of the head of the first left metatarsal, without systemic upset or restriction of joint movement but producing pus with large numbers of *S. aureus* and showing three calcific fragments of sesamoid in the sinus track on X-ray examination (*Fig.* 4).

Osteomyelitis of the medial sesamoid was diagnosed, and further rest and flucloxacillin prescribed in the expectation of spontaneous extrusion of bony fragments, but little improvement followed and the sinus track with its contained sequestra was excised *in toto* on 24 March 1977. Histology, in addition to confirming the diagnosis, revealed a vigorous tenosynovitis in the adjacent fibres of the flexor hallucis brevis tendon. Healing was complete within 3 weeks and follow-up at 1 year after presentation indicated complete cure.

Conclusion

The delay in clinical diagnosis and in interpretation of radiological signs and the late sequestration are characteristic of the condition described, and have been discussed, in particular, by Rowe (1963) and Colwill (1969). It seems that we are slow to learn. Few cases of haematogenous sesamoid osteomyelitis are seen. Nearly all those reported have been in children and adolescents and in this age group it assumes relative importance as a consequence of the rarity of other conditions in the differential diagnosis. Osteomyelitis (White and Dennison, 1952), primary septic arthritis (Borrella et al., 1963), gonococcal arthritis (Fink, 1965) and tuberculous arthritis (Harris and Coulthard, 1942) are all unusual in the forefoot. Gout and pseudogout are extremely rare in the first two decades (Hollander, 1972) and the former has been reported only in association with rare specific syndromes (Riley, 1960; Decker and Vandeman, 1962; Lesch and Nyhan, 1964). Juvenile rheumatoid arthritis and rheumatic fever seldom present affecting single small joints.

Suspicion should therefore be aroused in a young patient with acute first metatarsalgia. Careful radiological examination of the sesamoids has a high probability of establishing the diagnosis. Whether or the natural history of the condition is affected by earlier diagnosis, appropriate counselling of the patient and the parents should be possible at an early stage.

Simple closure of perforated duodenal ulcers

Sir,
The article by M. J. Playforth and M. J. McMahon (*British Journal of Surgery*, **65**, 699–701) is an interesting summary of the experience at Leeds of simple closure of a perforated duodenal ulcer, but the authors' conclusions are surely totally unjustified. As they themselves point out, the information is entirely retrospective and in the absence of any figures at all for 'definitive' management of the first time perforated duodenal ulcer how can statements be made that 'the operation of simple suture of a duodenal ulcer is indicated only in young and middle-aged women' or 'our data do suggest that a lower operative mortality might result from the addition of a definitive procedure to closure of the perforation . . .' Presumably some information is available, since 62 of their patients had some form of management other than simple closure.

Personally I shall continue to oversew perforated duodenal ulcers unless there is a clear indication at the time of laparotomy that a complication may follow from not undertaking a definitive procedure, e.g. a second posterior chronic duodenal ulcer, or until a properly controlled prospective trial indicates results superior to those of the more major procedure. With careful postoperative follow-up those patients requiring subsequent definitive ulcer surgery can be selected, and in this respect it is interesting to note that six out of their eight 'ulcer-related complication' deaths occurred a considerable time (1–84 months) after simple closure.

M. H. JOURDAN

Department of Surgery
Guy's Hospital
London SE1 9RT

Sir,
The aim of our communication was to indicate that curative surgery for perforated duodenal ulceration (simple closure of the ulcer) carried a significant risk to life, due in part to the continued presence of the ulcer. It is common to find the tacit assumption that this procedure represents the baseline of safety in the management of perforating ulcers, and that more definitive measures confer the sole advantage that some patients will be spared a subsequent elective operation, albeit at the expense of an increased risk to health during the acute illness.

Thus, we were only concerned with those patients who actually underwent simple closure of the ulcer and did not wish to become embroiled in rather meaningless comparisons with the results from patients who had received a definitive procedure at the time of closure of their perforation. For the record, at the time of perforation closure, 2 patients received a partial gastrectomy and 20 a highly selective vagotomy, without mortality. Truncal vagotomy was carried out in 26 patients with 1 death (respiratory) and 14 were managed conservatively with 3 deaths. No complications resulting from the continued presence of an ulcer were seen in any of the patients who received an emergency definitive procedure. These patients clearly form a highly selected group and the results of their definitive treatment were predictably good.

As we pointed out in the paper, we were seeking evidence of disaster during follow-up. Incompleteness of the follow-up data was almost inevitable in a study of this type; more complete follow-up, however, could only *add* to the complications we found, and thus strengthen our case.

Personally, I would rather that my perforation, should it arise, *is* treated by a definitive procedure, carried out, needless to say, by a surgeon of my own choice.

Abdominoperineal excision of the rectum

Sir,
Since 1964, when doing this operation I have commenced by cystoscopying the patient and passing retrograde ureteric catheters on each side.

This adds 20 min to the operation at the beginning, but I can assure you that it saves many more than 20 min during the operation, and I now take a delight in demonstrating to my assistant how he can find the ureters literally with his eyes shut!

I have been unable to find this procedure in any book on operative surgery and it may well be that it does not deserve mention. However, to those who have not employed it, I would recommend a try, if only for the saving of wear and tear on the surgeon's coronary vessels.

Book reviews

Advances in Surgery, Volume 11

Edited Charles Rob. 228 × 150 mm. Pp. 415 + xii. Illustrated 1977. London: Year Book Medical Publishers. £16·30.

THE eleventh volume of *Advances in Surgery* maintains the established policy of concise and comprehensive reviews of topics of current interest, and contains much of value for all surgical tastes. The recent impact of ultrasonography in the diagnosis of intra-abdominal lesions is acknowledged in a well-illustrated review, and, although not such a recent development, a section on microvascular surgery describes the more up-to-date applications in plastic and hand surgery, neurosurgery and urology. The more technical and 'craft' elements of surgery are covered by reviews of ulcerative colitis and Crohn's disease in the large bowel, the surgery of arterial embolism, injuries to metacarpal bones and joints and the use of adjuvant oncotherapy in the treatment of systemic micrometastases.

For those with interests in care of patients before and after operations there are chapters on hyperalimentation, monitoring of critically ill patients, problems with postoperative drug therapy and the respiratory distress syndrome. This book has, therefore, a little bit of succour for every surgeon who thirsts for something new and interesting.

The style of presentation is good and the factual content of each chapter is well judged; for example, the chapter on hyperalimentation by Joseph Fisher is over 60 pages in length but is essentially practical in the approach, describing techniques of administration and clinical application with a minimum of metabolic 'journalese' so that it remains intelligible to those who do not have a special interest. This is a worthwhile addition to the series of *Advances in Surgery*.

R. G. CLARK

Atlas of Surgery in the First Six Months of Life

S. Frank Redo. 245 × 195 mm. Pp. 188, with 300 illustrations. 1978. Maryland: Harper & Row. $27.50.

THIS atlas was conceived as a companion work to the volume entitled *Principle of Surgery in the First Six Months of Life* by the same author. The procedures commonly performed in the first 6 months of life are described. The operative techniques are clearly and concisely described and are well illustrated by halftone drawings. The technical details are supplemented by diagnostic and preoperative considerations and suggestions for postoperative management.

It was surprising to find a section on appendicectomy, a procedure rarely undertaken as such in the first 6 months. Moreover, some of the procedures and technical details are clearly out of date. In particular, I would mention duodenojejunostomy, which has been superseded by duodenoduodenostomy, a two-layer intestinal anastomosis which has virtually been abandoned in favour of a single-layer technique and open rectal biopsy has been replaced by the suction biopsy in all but a few selected cases. Oesophageal atresia repair by the entire extrapleural approach has resulted in a much improved mortality and morbidity rate when compared with the transpleural approach described by the author. The section on inguinal hernia in the male includes a description of inguinal herniorrhaphy. Most paediatric surgeons consider this unnecessary and limit the procedure to an inguinal herniotomy. A paramedian abdominal incision is preferred throughout. This is in contradistinction to the transverse incision used by most paediatric surgeons.

The cost of the atlas is £17·90 compared with £42·50 for the paediatric surgical volume edited by H. H. Nixon in the Operative Surgery series of Charles Rob and Lord Smith which is a much more comprehensive and valuable work.

L. SPITZ

Notebook of Medic[illegible]

[illegible] s prep[illegible] [illegible] postgraduates, but [illegible] clinical medical students. The first section [illegible] the usual range of endocrinology relate[illegible] surgery; the second section consists of ch[illegible] physiology, fetal physiology, perinatal and n[illegible]. Each chapter consists of a descriptive text in terse, not[illegible] with many charts and flow diagrams, followed by a number of multiple-choice questions based on the material presented and finally the key to the correct answers of the multiple-choice questions. The idea is that the student first refreshes [illegible] memory of previous reading and subsequently can test him[illegible] with the multiple-choice questions.

The real problem with this book is that it aims to cover the physiology of endocrinology at all levels from the medical student upwards. This means that a good portion of the book is too complicated for the medical student, and there are similar problems with regard to the material of gynaecological and obstetric interest compared with the material needed by surgeons and physicians. It seems likely that a student in any particular category may be reluctant to pay the cost of this book in order to cover only one small aspect of physiology, knowing that much of it would be inappropriate to his needs.

MICHAEL HORSLEY

Gynecologic and Obstetric Urology

Edited H. J. Buchsbaum and J. D. Schmidt. 260 × 180 mm. Pp. 461 + xiv. 1978. Philadelphia: Saunders. £24·00.

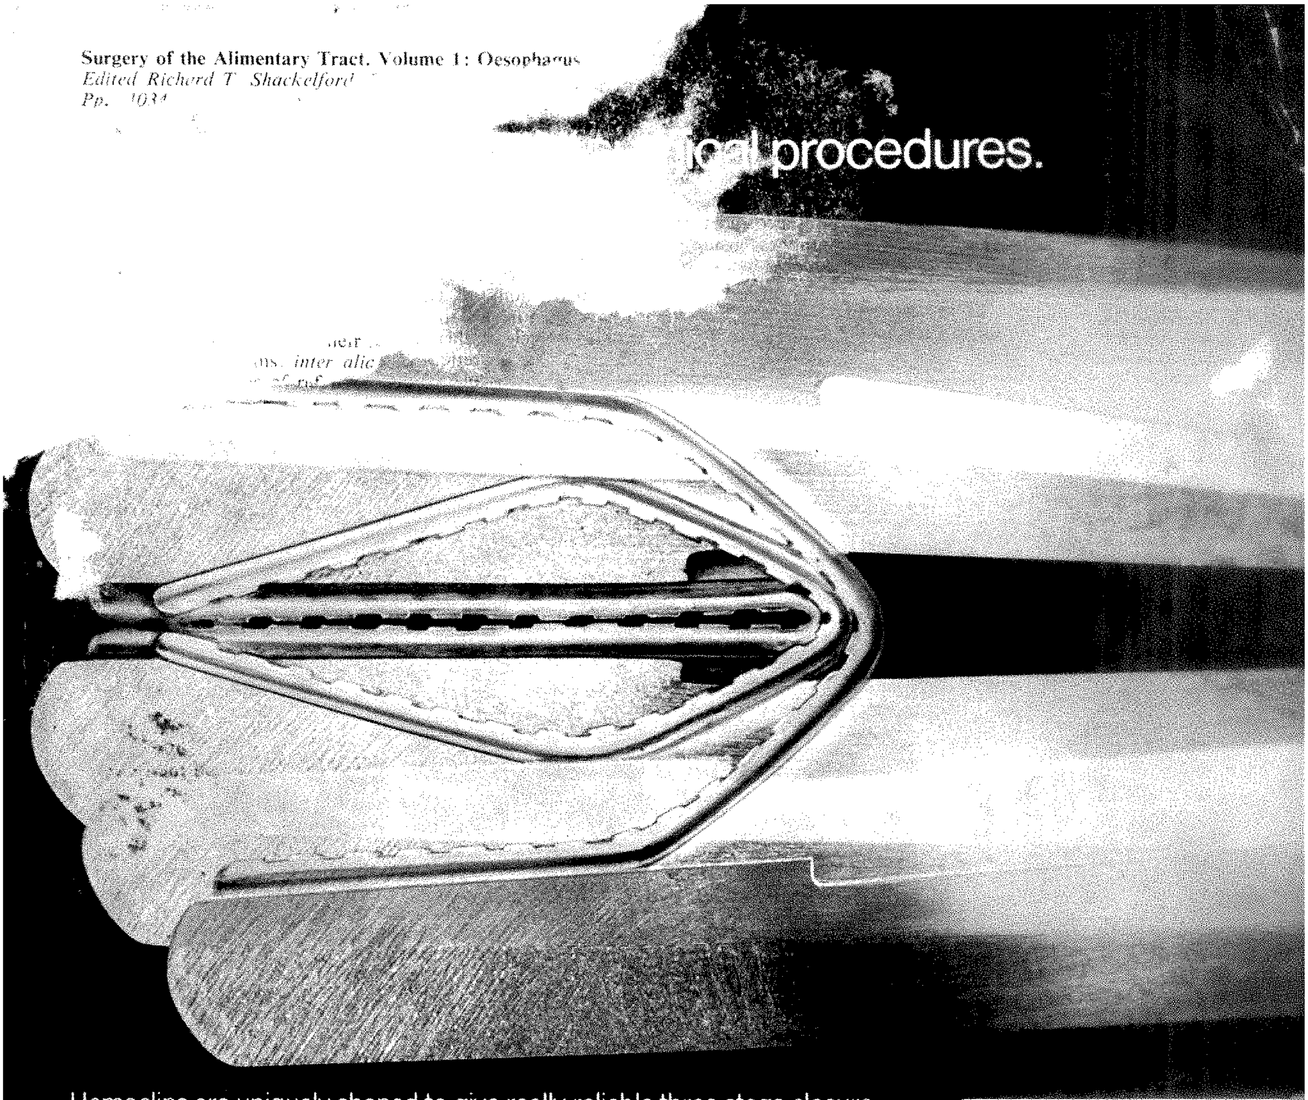
GYNAECOLOGISTS and urologists have for too long muttered threateningly about each other from opposite sides of the patient with a damaged ureter or misdiagnosed pelvic mass. This book reinforces the growing trend of reconciliation between these two specialties whose areas of interest are so close and who so often need each other's advice. The introduction to the book rightly deplores the inadequate training of gynaecologists in female urology and of urologists in gynaecology.

This multi-author textbook, originating from the Departments of Gynecology and Urology of the University of Iowa, aims to correct this defect. It is written particularly for the gynaecologist in training, 20 of its 31 authors being gynaecologists. The book starts with several excellent chapters on female genito-urinary embryology, anatomy and physiology. There follows a section of four chapters on the common urological problems met in gynaecological and obstetric surgery. These are short, well-written chapters with clear and useful diagrams. The third section, on various aspects of urinary incontinence and fistulas, includes no less than five separate chapters on operations to cure stress incontinence; most of the favourite operations are included but, unfortunately, some of the dogmatic statements only help to emphasize how little we really understand about urinary control mechanisms. There are then some comprehensive chapters on urinary tract infections and urinary tract involvement in gynaecological malignancy. Finally, there is an interesting section on the effect of pregnancy on renal function and the urinary tract.

It is not difficult for the individual surgeon to find favourite ideas and procedures omitted from this book, but for both the gynaecologist and urologist in training it can be thoroughly recommended as bridging the gap between these two specialties which have so many patients with problems common to them both.

EUAN MILROY

Surgery of the Alimentary Tract. Volume 1: Oesophagus
Edited Richard T Shackelford
Pp. 1034



Hemoclips are uniquely shaped to give really reliable three-stage closure action. Firstly, they are easy to position. Secondly, they close first at the tip, ensuring that the vessel will not slip out during compression.

And thirdly, the jaws are cross serrated for extra grip to give positive and complete occlusion.

Four different clip sizes, sterile, are available to meet all operative requirements and there is a choice of no less than twenty different types of applying forceps.

All Hemoclip products are available from Downs Surgical, so send the coupon now for full details.

But you [illegible]
see a staph. infection. — The [illegible] jur[illegible]
needs an ubiquitous antibiotic — pene[illegible]
all the tissues of the body and effective
wherever staphylococci are found.
Any staphylococcal infection
in hospital is a candidate
for Fucidin.

Since you can't pigeon-hole staph, you can't pigeon-hole fucidin

FUCIDIN (sodium fusidate B.P.)

Dosage:

Adults: 500 mg (2 capsules) 3 times daily with food.

Children: 20-40 mg/kg body weight daily in 3 divided doses with food.

The standard dose may be doubled for initial therapy in severe infections.

Adverse reactions and precautions:

After 14 years of widespread clinical use no pattern of toxicity to Fucidin has emerged. Gastro-intestinal upset occurs in some patients taking oral Fucidin. This can be minimised by taking the capsules with food or using Fucidin Enteric Coated Tablets. In some patients treated with either oral or I.V. Fucidin, jaundice has been reported. It has been extremely difficult to decide whether Fucidin, other drugs or the infection itself was responsible. Fucidin is excreted mainly in the bile and liver function tests should be carried out in patients with liver dysfunction, when used for prolonged periods or when administered in conjunction with other drugs which may compete for the same excretory pathway.

Product Licence No: 0043/5019.

Each capsule contains 250 mg sodium fusidate B.P.

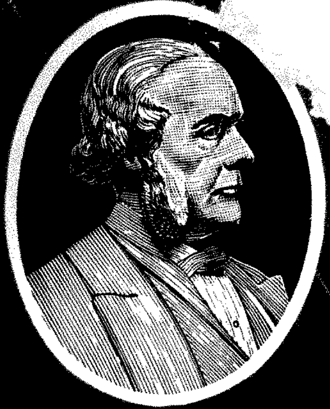
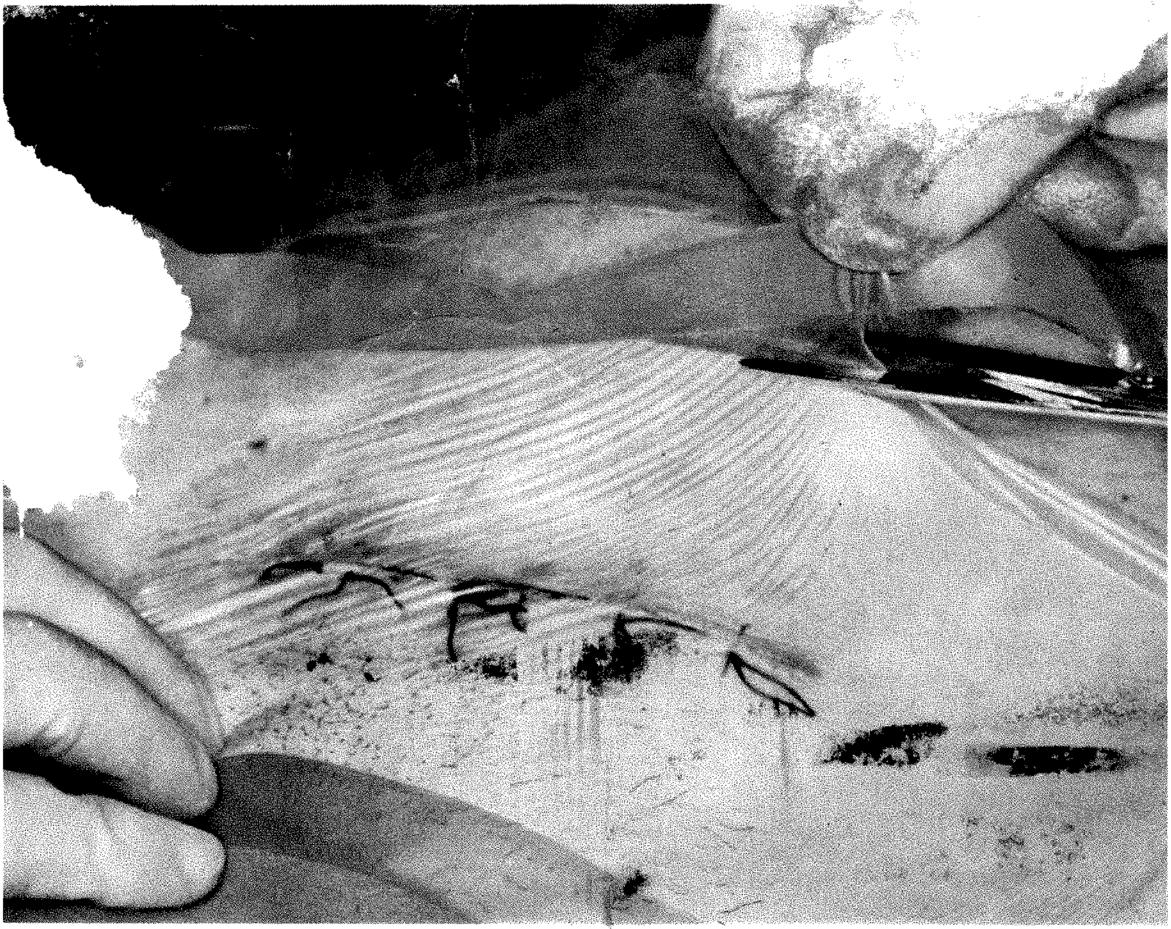
Op-Sit



British Journal of Surgery

The latest visual aid [illegible] in post-operative [illegible]



Op-Site represents a significant advance in post-operative care. The transparent film allows constant wound observation without the need for removal, reducing the frequency of dressing changes. Not only does this save time and minimise patient discomfort, but it also reduces the risk of secondary infection–obvious benefits to the surgeon, nurse and patient.

In addition, by maintaining the wound in a moist state, Op-Site provides an optimum wound healing condition.*

Op-Site gives strong, conformable, protection and can be applied quickly and easily. Since it is waterproof, the patient can bathe without fear of wound contamination.

Op-Site is a Smith & Nephew product. Samples and a fully-illustrated leaflet are available on request.

ACUPAN

tablets and injection/ nefopam hydrochloride

there's no analgesic like it

"a potent analgesic of novel structure and unique physiological properties."[1]

1 *Journal of Clinical Pharmacology* (1976) **16**:34

Acupan is a [illegible] daily [illegible] unrelated to any [illegible] gesic now [illegible] prescribed.

Acupan has been [illegible] oven effective [illegible] controlling [illegible] n associated w[illegible] a wide range of co[illegible]

Acupan brings to the treatment of pain specific and unique properties which make it the ideal strong analgesic in many patients.

Acupan is backed by a wealth of clinical evidence. It has been favourably compared with virtually all commonly used analgesics.

Acupan has an acceptable level of side-effects for a strong analgesic, as established in over six years of clinical use.

Acupan fits into the management of pain precisely where the choice of agent is most difficult.

Acupan is effective by mouth and by injection.

Acupan is not subject to narcotic restrictions.

ACUPAN

your patients will appreciate the difference

PR[illegible]UCT

Acupan prescribing information

Composition

Acupan tablets
Each tablet contains nefopam hydrochloride 30 mg.
Acupan Injection
Each 2 ml ampoule contains 1 ml of a solution of nefopam hydrochloride 20 mg/ml.

Indications

Acupan is indicated for the relief of acute and chronic pain, including: post-operative pain; dental pain; musculo-skeletal pain; acute traumatic pain and cancer pain.

Dosage and administration

Adults
Acupan tablets
The recommended starting dosage is one tablet three times daily. Dosage may range from one to three tablets three times daily depending on response.
Acupan Injection
20 mg (1 ml) intramuscularly or intravenously repeated if necessary every six hours. Onset of effect after intramuscular injection is within 15 to 20 minutes and peak effect is reached at one to one-and-a-half hours after administration.
For further information on the administration of *Acupan* Injection please refer to data sheet.
Children
Since *Acupan* has not been evaluated in children no dosage recommendation can be given for patients under 12 years.

Side-effects

Nausea, nervousness, dry mouth and lightheadedness may occur. Less frequently, vomiting, blurred vision, drowsiness, sweating, insomnia, headache and tachycardia have been reported.

Caution

The side-effects of *Acupan* may be additive to those of other agents with anticholinergic or sympathomimetic activity. It should not be used in the treatment of myocardial infarction since there is no clinical experience in this indication. Hepatic and renal insufficiency may interfere with the metabolism and excretion of nefopam.

Contra-Indication

Acupan is contra-indicated in patients with a history of convulsive disorders.

Basic NHS prices

Acupan tablets: Bottle of 100 tablets £14.00
Acupan Injection: Box containing 5 ampoules: £4.00

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND

1980 MOYNIHAN FELLOWSHIP

The Association of Surgeons of Great Britain and Ireland invites applications for the Moynihan Fellowship up to the value of £2000.

The object of the Fellowship is to enable the holder (usually of the status of a young consultant or senior registrar) to broaden his surgical education by visiting clinics at home and abroad.

Candidates, who must be resident in the United Kingdom or Eire, but who need not be either Fellows or Associate Fellows of the Association, should state clearly in their application their programme and what they hope to achieve. If they intend holding the Fellowship in conjunction with any similar grant they should give details. They should also give short accounts of their past careers and present appointments. The names of two sponsors should be given. The Council will expect a report of the visit at its conclusion, and the Fellow may be invited to address the Annual General Meeting of the Association.

Applications (*ten copies on A4 paper*) must be submitted to the Honorary Secretary, Association of Surgeons of Great Britain and Ireland, at The Royal College of Surgeons, 35/43 Lincoln's Inn Fields, London WC2A 3PN, *by 1 October 1979*. Applicants should be prepared to attend for interview if they are requested to do so.

June 1979

ADRIAN MARSTON,
Honorary Secretary.

Danol

danazol

controls pituitary gonadotrophins without exerting oestrogenic or progestogenic activity

WINTHROP

For the treatment of endometriosis, infertility associated with endometriosis, fibrocystic mastitis, virginal breast hypertrophy, gynaecomastia, primary constitutional precocious puberty and other similar endocrine disorders where control of the release of pituitary gonadotrophins LH and FSH would be of therapeutic value.

Danol (danazol 200 mg). PL 0071/0095. Bottles of 100 capsules. Basic N.H.S. cost of one day's treatment £1.42 (3 capsules).
Danol-½ (danazol 100 mg). PL 0071/0094. Bottles of 100 capsules. Basic N.H.S. cost of one day's treatment 72 p. (3 capsules).
Dosage. Adults 200-800 mg daily, children 100-400 mg daily. See Data Sheet for details.
Contra-indications: Pregnancy.
Precautions. 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop.
Side Effects. Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control.
Danol is a trade mark. Further information available from:– Winthrop Laboratories Surbiton-upon-Thames Surrey KT6 4PH.

NEUROSURG

Consultant Editor: Lindsay Sym

This volume reviews the common neurosurgical procedures and embraces the essen points in the management of neurosurgical cases in relation to operation.

In this new edition, the detailed coverage of individual procedures, presented by acknowledged experts, has been increased and the significance of surgery when considering expected results has been included in many cases. The current, somewhat controversial role of chemotherapy in the management of cerebral tumours has been reviewed since operative surgery, particularly of gliomas, can no longer be considered in isolation.

The young surgeon will be provided with a wealth of accessible operative detail upon which to build his ow experience, while the more experienced surgeon who must undertake operations with which he is relatively unfamiliar will find invaluable guidance.

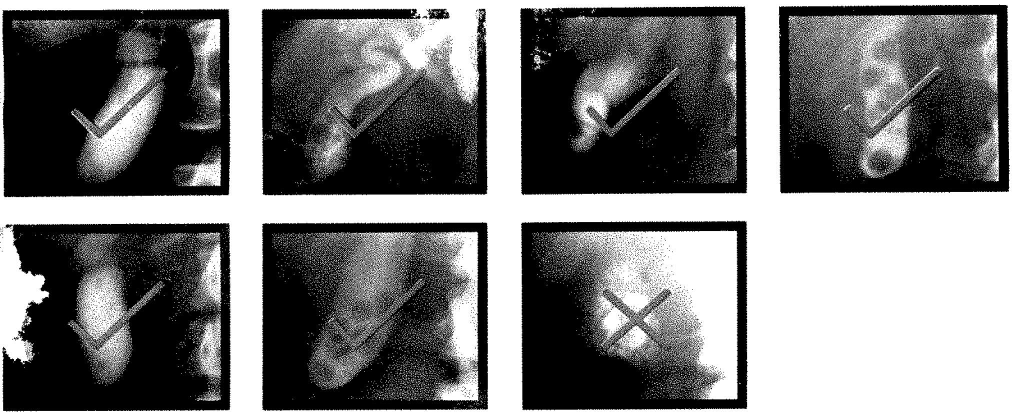
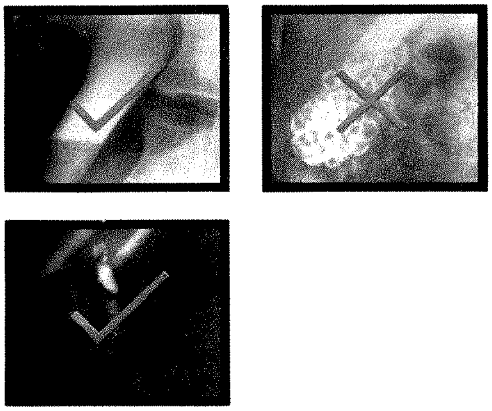
Chendol

What proportion [illegible]stones are suitable?





80%

Chendol can remove gallstones without surgery

Chendol solubilises 80% of all gallstones

CHENDOL acts on all mixed stones and cholesterol stones that are not calcium coated by reducing the amount of cholesterol secreted into the bile. Precipitated cholesterol is solubilised.

INDICATIONS For dissolution of gallstones. Cholesterol stones coated with calcium, or stones composed of bile pigments are not dissolved by chenodeoxycholic acid.

DOSAGE The present clinical evidence suggests that optimum results will be obtained on a dose level of 10–15 mg per kg body weight daily in divided doses.

CONTRAINDICATIONS, WARNINGS, ETC. CHENDOL should not be administered to patients with radio-opaque calcified gallstones nor to patients with non-functioning gallbladders.

CHENDOL should not be administered to women who may become pregnant not to patients with chronic liver disease, nor with inflammatory diseases of the small intestine and colon.

CHENDOL is generally well tolerated, the only side effects reported to date are diarrhoea and pruritus. It has been found that after a slight reduction in dose for a few days, diarrhoea ceases and the dose can then be gradually increased to the former level. Laboratory monitoring should accompany treatment.

Each CHENDOL capsule contains 125 mg of chenodeoxycholic acid.
Available in securitainers of 100 capsules — N.H.S. cost £13.50 per pack.
500 capsules — N.H.S. cost £65.00 per pack.

Results of recent studies have demonstrated a 93% success rate in the U.K.[1] and 81% in the U.S.A.[2] for solubilising cholesterol rich radiolucent gallstones in suitable patients.

Anaerobic Bacteria

'…the major cause of sepsis after sur
the gastrointestinal tract
or female genital
tract'.

Br. Med. J. i, 318, 1976

NOW

FLAGYL

METRONIDAZOLE

INJECTION

FOR INTRAVENOUS INFUSION

proves decisive in anaerobic infections

Only with recent improvements in bacterial culturing techniques has the pathogenic role of anaerobes in post-surgical infections been fully recognized.[1-3] Now 'Flagyl' Injection offers you a decisive means of treating these infections – which are often life-threatening and often resistant to established antimicrobials. The response to 'Flagyl' Injection is rapid and dependable,[2] as it is consistently bactericidal to pathogenic anaerobes at tissue concentrations easily achieved in treatment. Bacterial resistance is not a problem,[2-4] and 'Flagyl' is highly acceptable – as eighteen years of use in other indications has established.

Dosage: Treatment: adults and children over 12 years: 100 ml by intravenous infusion eight-hourly, administered 5 ml per minute. Oral medication with 400 mg three times daily should be substituted as soon as this becomes feasible. Treatment for seven days should be satisfactory in most cases. Children under 12 years: as for adults but the single intravenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight and the oral dose on 7.5 mg per kg bodyweight. Prevention: adults and children over 12 years: 100 ml by intravenous infusion immediately before, during or after operation, followed by the same dose eight-hourly until oral medication (200 to 400 mg three times daily) can be given to complete a seven-day course. Children under 12 years: as for adults but the single intravenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight and the oral dose on 3.7 to 7.5 mg per kg bodyweight. Precautions: pregnancy; lactation; clinical and biological surveillance if recommended duration of treatment exceeded; dosage may be halved for patients with renal failure; avoid alcohol; if 'Flagyl' is to be given to patients receiving oral anticoagulants the dosages of the latter should be recalibrated. Side effects and adverse reactions: occasionally an unpleasant taste, furred tongue, nausea, vomiting (very rarely), gastro-intestinal disturbance. Drowsiness, dizziness, headache, ataxia, skin rashes, pruritus, inco-ordination of movement, darkening of the urine very rarely. During intensive and/or prolonged therapy, peripheral neuropathy has been reported. A moderate leucopenia has been reported but the white cell count has always returned to normal before or after treatment has been completed. Transient epileptiform seizures in a few patients undergoing intensive, high-dosage metronidazole radiosensitization therapy.

Conservative surgery in reflux stricture of the oesophagus associated with hiatal hernia

K. MOGHISSI*

SUMMARY

During a 7-year period, 130 patients with oesophageal stricture resulting from long-standing reflux oesophagitis and hiatal hernia were referred for surgery. Eighty-seven of these patients underwent conservative surgery consisting of intraoperative transgastric retrograde dilatation combined with one of two types of anti-reflux operation: in 34 patients (group 1) an Allison-type operation for hiatal hernia was undertaken, and in the remaining 53 patients (group 2), a Nissen-type fundoplication was carried out. In 22 patients in this latter group the oesophagogastric junction could not be brought down into the abdomen in spite of extensive oesophageal mobilization and the fundoplication was finally placed above the diaphragm.

From the successful results in both groups (particularly in group 2), it is concluded that conservative surgery should be considered in cases of hiatal hernia with a reflux stricture that yields to intraoperative dilatation.

THE rational approach to the management of reflux oesophagitis with stricture involves the relief of the obstruction and the prevention of further gastro-oesophageal reflux that would otherwise cause recurrence of the stricture. Radical surgery involving excision of the stricture requires reconstruction of the upper alimentary tract using the stomach, jejunum or colon. This is inevitable in a number of cases but in many patients a more conservative approach may be employed.

This paper is a review of such a conservative approach in a personal series of patients treated over a period of 7 years. In the light of this, and a review of the literature, the place of conservative surgery in oesophageal stricture following reflux and hiatal hernia is discussed.

Patients and methods

In the past 7 years a total of 130 patients with long-standing hiatal hernia and reflux stricture was submitted to operation. Cases of oesophageal stricture without a demonstrable hiatal hernia are not included. Forty-three patients underwent resection of the stricture and reconstruction of the oesophagus. This group of patients is not presented here but is mentioned later in the discussion when appropriate. The remaining 87 patients underwent conservative surgery consisting of intraoperative dilatation of the stricture and an anti-reflux operation.

Patients were selected for conservative or radical surgery according to the following criteria.

1. The severity of the stricture, judged on the results of oesophagoscopy and barium contrast studies, but essentially by its response to bouginage.
2. The severity and extent of pathological changes affecting the oesophageal wall, such as transmural fibrous scarring and the existence of a penetrating ulcer or perforation.

On the whole, conservative surgery was undertaken in the absence of a perforation or ulcer penetration and when the stricture could be dilated at the time of operation. In the majority of patients this decision could be made before surgery. In some cases, however, this was not possible.

Of the 87 patients, 49 were male and 38 female. Their ages ranged from 18 to 84 with an average of 62·2 years. The outstanding symptom of every patient was dysphagia: total dysphagia was present in 3 patients and the others could only manage a liquid and purée diet. The mean duration of dysphagia was 2·5 years. Every patient had undergone dilatation at least twice before admission for surgery. Fifteen of these patients had been treated elsewhere by repeated dilatations for a period of 1–10 years and were referred for surgery when the stricture was judged to be undilatable. Three patients had been practising daily self-bouginage for a period of 2–4 years. Six patients had had previous surgery for repair of a hiatal hernia.

Loss of weight averaging 6 kg was recorded in 30 patients. Anaemia was present in 10 patients and 6 others had acute bleeding, 3 of them with severe haematemesis at the time of admission.

Preoperative investigations included a barium swallow examination, oesophagoscopy and biopsy. The barium swallow demonstrated a stricture and hiatal hernia in every case.

The majority of patients had had previous barium swallow examinations, showing a hiatal hernia and stricture, from 1 to 18 years before admission.

Oesophagoscopy was carried out in every patient. The endoscopic characteristics and the level of the stricture from the upper alveolus were carefully recorded. Biopsies were taken from above, at the stricture and, when possible, from below it. Based on oesophagoscopic findings and bouginage a stricture was empirically classed as 'tight' when it was rigid and unyielding to the passage of bougies and 'moderately tight' when it was resistant and gripping but allowed the introduction of bougies of increasing diameter. A stricture was classed as 'not tight' when it allowed easy introduction of bougies of increasing diameter and offered no resistance to their passage. All patients in this series had a 'tight' or 'moderately tight' stricture (*Table I*).

The approximate overall length of the oesophagus and the level of the oesophageal hiatus for each patient were recorded using a technique similar to that described by d'Abreu et al.

(1971). From the endoscopic level of the stricture, the result of the barium swallow and the approximate length of the oesophagus, the location of the stricture in relation to the aortic arch and the diaphragmatic oesophageal hiatus were determined and recorded. In this way a comparable anatomical level of all the strictures, irrespective of the patient's size, was obtained. A stricture was classed as low when it was situated within 4–5 cm of the predicted oesophageal hiatus of the diaphragm and high when it was above this level. In this series, no stricture was situated above the aortic arch (*Table II*).

Operation

The operative approach consisted of a left thoracotomy in every case and the thoracic oesophagus was fully mobilized by [illegible]unt o[illegible] [illegible] Ac[illegible] abdomen was obtained [illegible]rcum[illegible] [illegible]dial [illegible] [illegible]erally placed diaphrag[illegible]. The [illegible] was e[illegible]ed first digitally through [illegible] location an[illegible] relationship with the hiatus [illegible]oesophagogastric juncti[illegible] were noted. The level of the [illegible]ageal membrane [illegible]ligament[illegible] indicating the [illegible]tric junction was also deter[illegible]ned and recorded [illegible] (*Table III*), using the preoperative criteria for [illegible] stricture as indicated previously. Transgastric [illegible] the stricture was then carried out by retrograde [illegible]gar bougies of increasing diameter, up to and [illegible]ng[illegible]m, introduced by one hand and guided by the [illegible]pl[illegible] over and around the oesophagus. Following the [illegible]tio[illegible] gastric incision was closed and one of two types [illegible] operation carried out. Thirty-four patients [illegible]p[illegible] [illegible]a[illegible] an Allison (1951) repair and 53 patients (group [illegible] Nissen (1956) fundoplication. In the latter the aim was [illegible] [illegible]bilize the oesophagus in order to bring the oesophagogastric junction, surrounded by the fundus of the stomach, below the diaphragm.

In 31 patients (group 2A) this was achieved, and this procedure is referred to as intra-abdominal fundoplication. In the remaining 22 patients (group 2B), in spite of full mobilization, this could not be achieved. Therefore, the fundoplication was placed permanently in the posterior mediastinum above the diaphragm. This is termed intrathoracic fundoplication. In both groups 2A and 2B the hiatus was reconstructed (*Table I*).

The allocation of patients to either group 1 or group 2 was governed by the anatomical disposition of the hiatus, the level of the stricture and the oesophagogastric junction found at operation, and whether there had been previous surgery. Consideration was given to the fact that a satisfactory repair in an Allison-type operation requires the integrity of the crural fibres, whereas a fundoplication requires a mobile fundus, particularly when the fundoplication is to be placed in the chest.

It is therefore clear that allocation of patients to groups 1, 2A and 2B was largely made at the time of operation.

Results

Table I presents the total number of patients in each group and the type of stricture. *Table II* shows the number of patients with high or low stricture, and *Table III* indicates the number of patients in each group with the oesophagogastric junction located high or low.

There were 3 hospital deaths in the entire series, a mortality of 3·4 per cent. One patient died 7 days postoperatively from pulmonary embolus and an 84-year-old man died 17 days postoperatively from a chest infection. These 2 patients were in group 1. The third patient, from group 2A, died from a myocardial infarction 24 h after surgery. The 84 surviving patients have been followed up for 6 months to 6 years (*Table IV*).

Group 1

There were 34 patients in this group, 14 with a tight stricture and 20 with a moderately tight stricture. Thirty-two patients survived the operation and 4 needed postoperative dilatation in the first year after surgery. One of these has residual dysphagia and awaits further surgery. Two other patients have no dysphagia but suffer from medically manageable heartburn and have evidence of reflux. The remaining 26 patients are asymptomatic. It is relevant to point out that each of the 4 patients who required postoperative dilatation had had a tight stricture before surgery. Also there were 2 high and 32 low strictures in this group. The 2 patients with high strictures are those with the residual symptoms of heartburn and reflux.

Group 2A
There were 31 patients in this group, 10 w[illegible] stricture and 21 with a moderately tight st[illegible] stricture was high in only 2 patients. Th[illegible] survived the operation: of these, 1 pat[illegible] dilatation on two occasions in the first 6 m[illegible] operation. Preoperatively, this patient [illegible] moderately tight stricture. Two patients [illegible] symptoms of fullness after meals. Twenty-seven patients have remained asymptomatic.

Group 2B
There were 22 patients in this group, 15 [illegible] a high and tight stricture and 7 with a low stricture, which was tight in only one. In the latter 7 patients, despite the low position of the stricture, the fundoplication could not be placed below the diaphragm. However, it must be pointed out that 4 of these patients had had previous surgery for repair of a hiatal hernia. There was no postoperative mortality in this group and all the patients have remained asymptomatic.

Discussion
The literature concerned with reflux stricture of the oesophagus and its surgical treatment is controversial. The principal cause of this seems to be that the structural changes in the oesophagus in response to gastric reflux vary in severity and type. Consequently, the experience and therapeutic approach of various workers have differed. This is borne out by the many 'rational approaches' to the treatment of the stricture that have emerged in the past 24 years. These range from simple bouginage to various oesophagoplastic procedures following excisional surgery.

Most surgeons have advocated resection of the stricture and reconstruction of the upper alimentary tract whenever the general condition of the patient permits the proposed surgical undertaking. However, the choice of operation and the substitute have been subject to the surgeon's preference. Oesophagogastric anastomosis has been employed by Sweet et al. (1954), Ellis et al. (1956), Collis (1957), Gavriliu (1965) and Franklin (1977).

The use of the jejunum was originally advocated by Roux (1907), and since then this approach has been favoured by a number of surgeons—Allison and Da Silva (1953), Brain (1953, 1967), Allison et al. (1957) and Gunning (1972). The use of the colon to replace the oesophagus has been practised since 1911 when it was introduced by Kelling. Its use in cases of benign oesophageal stricture, however, has been greatly popularized by Belsey (1953, 1965; Skinner and Belsey, 1967; Belsey et al., 1972).

A more conservative surgical method not requiring resection of the stricture was advocated by Collis (1957, 1961). He devised the operation of gastroplasty and suggested dilatation of the stricture to relieve the obstruction coupled with gastroplasty as an anti-reflux procedure in cases of oesophageal stricture, particularly in those with a high oesophagogastric junction (acquired short oesophagus). Pearson and co-workers (Pearson et al., 1971; Pearson and Henderson, 1973, 1976), used a combination of a Collis gastroplasty and a Belsey hiatus hernia repair as an anti-reflux operation coupled with preoperative or intraoperative dilatation to relieve the obstruction in patients with stricture and acquired short oesophagus. They reported excellent results in a selected group of patients with follow-up extended over a [illegible] years. [illegible] gastroplasty [illegible] [illegible] repair have not been [illegible] shown recently by Orringer [illegible] 197[illegible] [illegible]less, the procedure app[illegible] class of stricture, when [illegible] oesophagus is not desirable, and in the presence of an acquired short oesophagus with a high oesophagogastric junction.

Although it is generally agreed that bouginage alone is not a permanent solution to the problem of a stricture, dilatation combined with an anti-reflux operation has a logical chance of success. Hayward (1961a) and more recently Hill et al. (1970) and Herrington et al. (1975) have pursued this line of treatment with success by dilating the stricture and reducing the hernia.

There is, however, confusion about the criteria adopted for either preserving or resecting a fibrotic scarred gullet. The level of the stricture has always been of importance when selecting patients for conservative or excisional surgery. Normally the oesophagogastric junction is found approximately 2–[illegible] cm below the squamocolumnar epithelial junction which corresponds externally to the level of [illegible] peritoneal reflection and the attachment of [illegible] phreno-oesophageal membrane (ligament). This [illegible] well documented by Lerch (1950) and Hayward (1961b, c). In cases of hiatal hernia and gastro-oesophageal reflux it is generally agreed that the stricture develops at the squamocolumnar epithelial junction. Even when the tip of the stricture was high in the oesophagus, Allison believed that it extended down to within millimetres of the columnar epithelium of the stomach. Hayward (1961a) believed this not to be the case. Hill et al. (1970) also found that the level of the stricture did not correspond externally with the oesophagogastric junction. Based on this, these authors were able to mobilize the oesophagus and bring the oesophagogastric junction below the diaphragm irrespective of the level of the stricture.

Careful study of our cases makes us believe that, although the lowest part of the stricture does generally correspond with the original location of the squamocolumnar epithelial junction and the site of attachment of the phreno-oesophageal membrane, this is not always so. The latter may be situated considerably higher than the oesophageal hiatus of the diaphragm. This conclusion was reached by noting and recording the site of the stricture in relation to the oesophagogastric junction at operation by means of inserting a finger (or a Hegar bougie in the case of a high stricture) through the gastrotomy.

Study of *Tables II* and *III* shows that in 19 patients the position of the stricture was high but in only 15 of them was the location of the oesophagogastric junction correspondingly high. In 4 patients (4·5 per cent), therefore, the level of the stricture was higher than the external demarcation of the oesophagogastric junction. In these 4 cases (2 in group 1 and 2 in group 2) the junction could be placed beneath the diaphragm. In 7 patients from group 2B, although the junction and the stricture were within 5–6 cm of the hiatus, an intrathoracic fundoplication was necessary.

The practical conclusions are: first, that in 4·5 per cent of cases the level of the stricture is higher than the oesophagogastric junction. Secondly, more attention should be focused on the level of the junction [illegible] f the stricture [illegible] to be placed [illegible] the hernia is [illegible] the reduction of the [illegible] upon the level of the [illegible] oesophageal membrane [illegible] and [illegible] pathological changes [illegible] phagus [illegible] the perioesophageal structures. Our experience is therefore that in those who [illegible] that the junction can [illegible] down below the diaphragm in all cases. The placing of the fundoplication in the [illegible] antireflux measure has been satisfactory [illegible] p 2B patients, and overcomes the impossible [illegible] ing to reduce the oesophagogastric junction [illegible] diaphragm at all costs. The final decision [illegible] the fundoplication in the abdomen or the [illegible] n, however, be made at operation. Based on experience, we believe that neither the level of stricture nor the shortness of the oesophagus [illegible] tutes a criterion for radical surgery. The criterion should be whether the stricture can be satisfactorily dilated or not. An undilatable stricture should be excised.

It also appears that the preoperative assessment of the tightness of the stricture affects the postoperative results when an Allison-type operation is undertaken, as shown by the persistence of residual postoperative dysphagia and stricture in 4 out of the 14 patients with a tight stricture in group 1. In group 2, however, preoperative tightness of the stricture had no effect on the postoperative results.

Although our records show that 43 (33 per cent) of the 130 patients had radical surgery, 6 of these had resection because of oesophageal perforation in the course of dilatation of severely fibrotic strictures. In 16 other patients the resection was planned because of previous surgery, bleeding and extensive ulceration. Only in the remaining 21 patients (16 per cent of all cases) was the decision to undertake resection of the stricture made because the stricture could not be satisfactorily dilated at the time of operation. Taking into account the 6 perforation cases, a total of 27 patients (20 per cent) had resection of an undilatable stricture.

In 4 of our patients a stricture high above the oesophagogastric junction could be placed under the diaphragm at operation. Allison (1970) suggested that a high stricture well above the oesophagogastric junction is not a reflux stricture but results from oesophagitis at the high junction of the squamo-columnar epithelium. The controversy over the concept of columnar epithelium lining the oesophagus started in 1950 when Barrett drew attention to the condition. Allison and Johnstone (1953), termed this 'oesophagus lined with gastric mucous membrane' and believed it to be congenital in origin, a claim which has been rejected in many subsequent papers, notably those by Goldman and Beckman (1960), Adler (1963), Mossberg (1966) and, more recently, Hill et al. (1970). These authors believe that this condition is an acquired one resulting from oesophagogastric reflux. It therefore appears that whilst there is a general acceptance of the concept of a columnar-lined oesophagus, there is also a considerable body of opinion against its congenital origin.

Although there is controversy about the aetiology of columnar epithelium lining the oesophagus, there is complete agreem[illegible] rding the conservative approach to the treat[illegible] of the stricture resulting from it, as recommended by Allison (1970), Neaf and Savary (1972) and Davidson (1976).

Conclusions

The decision to offer a patient with a hiatal hernia and long-standing reflux stricture conservative or radical surgery should not depend on the level of the stricture but on its response or 'give' to dilatation and on whether the oesophagus can be preserved. This is best assessed at operation, as the preoperative impression of the severity of the stricture and its response to dilatation does not always correlate with the findings at operation. Conservative surgery consisting of dilatation of the stricture and an anti-reflux operation should be considered in every patient.

In our experience, the best way to achieve dilatation of a tight fibrotic and scarred stricture is at operation through a gastrotomy by retrograde and guided passage of bougies.

There are several surgical methods to prevent reflux following dilatation of a stricture. An Allison-type operation may be suitable when the oesophagogastric junction can be brought down below the diaphragm and when the anatomical disposition of the diaphragmatic crura is suitable for such a procedure. These two factors impose a serious limitation in patients with a stricture, and even in suitable cases the method has not been entirely satisfactory.

A Nissen-type fundoplication as an anti-reflux procedure may be used with advantage in all cases irrespective of the site of the oesophagogastric junction. If the junction cannot be reduced below the diaphragm, the fundoplication, that is, the lower oesophagus surrounded by the stomach and the fundus should be left in the chest above the diaphragm. The only limitation of this procedure is in cases when the fundus cannot be mobilized. The fundoplication has real advantages, however, in those patients with an irreducible oesophagogastric junction who otherwise would have to be submitted to more radical surgery.

geal perforations with ce t an scopic method

GSNO

copic treatment of chr oesophageal per- (more than 18–24 h old) the application of ydroxide 20 per cent to the edges of the rfora- described. The importance of pleural and medi- toilet and the accurate siting of drainage tubes ull expansion of the lung together with measures diminishing oral, gastric and biliary secretions from perforation, are stressed.

Five patients who have been treated by this conservative method are presented and the method compared with the more radical surgery advocated by the majority of other surgeons.

PERFORATIONS of the oesophagus may occur in the cervical oesophagus or the intrathoracic oesophagus. The causes are instrumental, traumatic, or the result of spontaneous or strain-induced ruptures or intrinsic oesophageal disease.

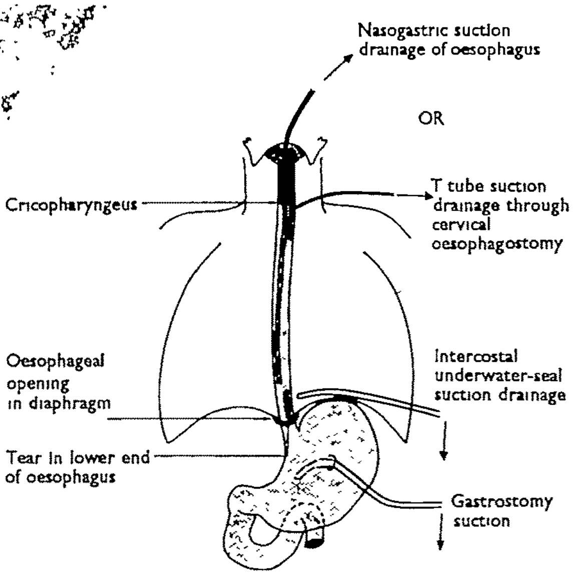
Cervical perforations

Perforations of the cervical oesophagus resulting in mild crepitus, extravasation of fluid but with no thoracic involvement are treated by oral and systemic antibiotics, by stopping oral feeds and by providing intravenous alimentation. Extensive leaks, causing widespread crepitus and dissection of extravasated material down the anterior or posterior mediastinum with a retro-oesophageal abscess, require operative drainage plus antibiotics and the feeding regimen outlined above. With proper and prompt treatment, perforations of the cervical oesophagus have a low mortality.

Thoracic perforations

Ever since Barrett's report (1947) of the successful repair of a spontaneous rupture of the oesophagus, the treatment of thoracic oesophageal perforations has been associated with a high mortality and morbidity. It is generally agreed that if a thoracic perforation is diagnosed within 18 h, the best results are obtained by primary suture of the perforation; the mortality rate then varies between 10 and 15 per cent. Surgical treatment after 18 h increases the mortality to 50 per cent. Any method, therefore, which can reduce this figure should be tried, and it is hoped that the method described below will go some way to achieving this.

Unfortunately, most thoracic oesophageal perforations are diagnosed after 18–24 h. By this time a severe and often fulminating chemical and infective mediastinitis and pleurisy are well established. These are caused by the aspiration of gastric, biliary and oral (often aggravated by dental sepsis) secretions through the perforation, by the intrathoracic subatmospheric pressure. The oesophagus is oedematous and friable and attempts at closure by suturing the defect are unsuccessful. The difficulty experienced in treating this condition is shown by the variety of surgical procedures reported.



Nasogastric suction drainage of oesophagus
OR
T tube suction drainage through cervical oesophagostomy
Cricopharyngeus
Oesophageal opening in diaphragm
Intercostal underwater-seal suction drainage
Tear in lower end of oesophagus
Gastrostomy suction

Fig. 1. Diagram showing siting of the drainage tubes.

For example, Thal (1968) uses a patch of the fundus of the stomach which is applied to the perforation. Urschel et al. (1974) apply an umbilical tape around the lower end of the oesophagus to occlude it and divert oral secretions by a cervical oesophagostomy in addition to suturing the perforation. Grillo and Wilkins (1975) use a pedicled pleural flap which is wrapped around the oesophagus. Pericardium may also be used in this way. Triggiani and Belsey (1977) prefer total resection of the oesophagus leaving the patient with a cervical oesophagostomy to divert swallowed saliva and a feeding gastrostomy, the cardia having been closed by sutures. A staged reconstruction at a later date with the left colon restores intestinal continuity.

Patients and methods

Since 1975 the Thoracic Surgical Unit at the Churchill Hospital, Oxford, has used a more conservative approach utilizing the following principles.

Treatment of shock: If the patient is shocked, resuscitative measures such as fluid replacement, antibiotics, digitalis, relief of pain and intercostal tube drainage are instituted until the patient is fit for operation.

Diagnosis: The diagnosis can be made from symptoms, signs and a plain chest radiograph showing mediastinal emphysema and/or a hydropneumothorax in the right or left pleural cavity. The diagnosis and site of a suspected perforation should, if possible, be confirmed by a Gastrografin contrast swallow. However, a negative oesophagogram does not rule out a tear (Defore et al., 1977).

Treatment: The following steps are then taken to establish drainage of the mediastinum and pleura and full expansion of the lung (*Fig.* 1). Mediastinal, pleural toilet and intercostal

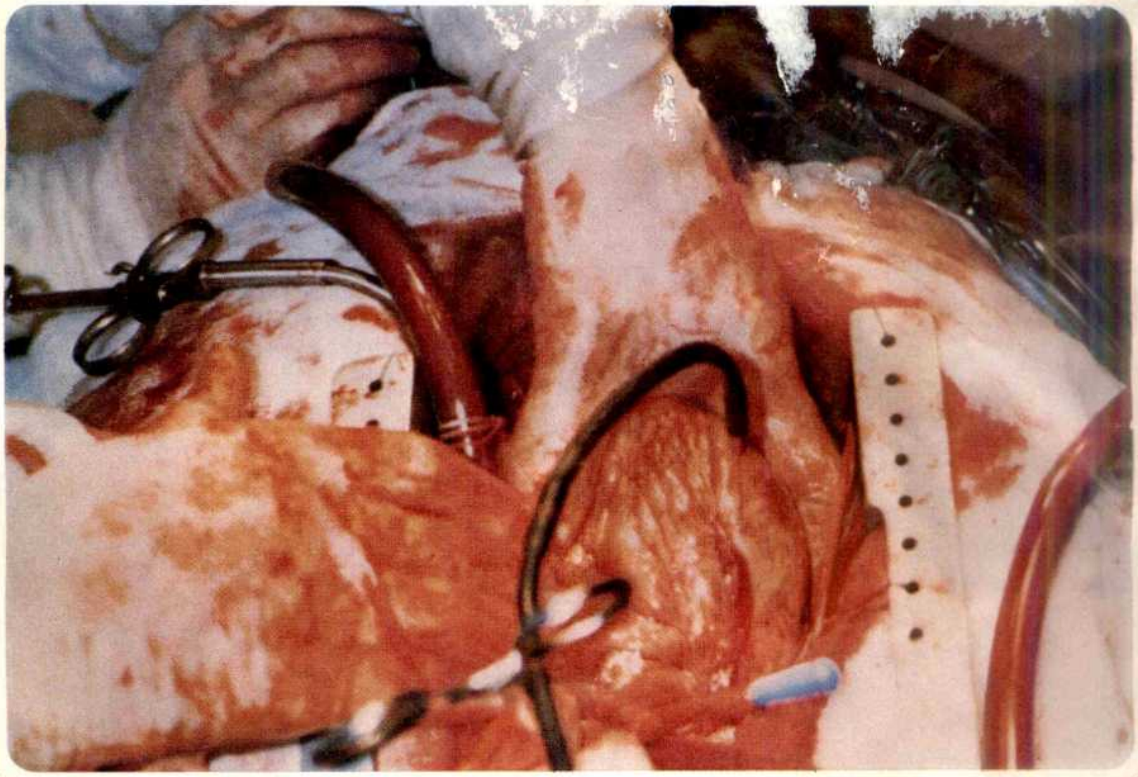
Magnapen

ampicillin/[illegible]



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

Prescribing Information

Magnapen Capsules: Black and turquoise capsules overprinted "Magnapen" containing 250mg ampicillin as Ampicillin Trihydrate B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Magnapen Syrup: Bottles containing powder for the preparation of 100ml suspension. When reconstituted each 5ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. with 125mg flucloxacillin as flucloxacillin sodium.
Magnapen Vials: Each vial contains 250mg ampicillin as Ampicillin Sodium B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Uses: Severe infections. Post-operative chest and wound infections. Prophylaxis in major surgery.

Dosage: Adult: 1 capsule or 10ml syrup, or 1 vial qid. Children: 2-10 years: ½ adult dose. Under 2 years: ¼ adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL0038/5001, 5009.
Contra-indications: Penicillin hypersensitivity, ocular administration.
Side-effects: As with other penicillins. An erythematous rash may occasionally occur, as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported, it is advisable to discontinue treatment.
Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product literature before using with intravenous fluids.

Basic N.H.S. Prices: (correct at time of printing Feb 79).
Capsules: 500mg, £18.06 (100 capsule pack).
Syrup: 250 mg per 5 ml, £3.18 (100ml).
Vials: 500mg, £7.45 (10 vials).

Magnapen is available to hospitals on regional contract dependent upon estimated usage.

Further information on Magnapen is available on request to the company.

Magnapen, BRL and the Company logo are registered trade marks.

INJECTABLE

ZINACEF

cefuroxime sodium

A MAJOR ADVANCE IN ANTIBIOTIC THERAPY

Zinacef is a new, broad spectrum, beta-lactam antibiotic offering important advantages for hospital practice. It is particularly appropriate for the treatment of serious, or potentially serious infections where the causative organisms have not been identified or may be mixed.

Greatly enhanced stability to beta-lactamases

The value of commonly used beta-lactam antibiotics is being constantly eroded by the growth of resistant populations of bacteria.
Zinacef has a unique chemical structure with in-built protection against beta-lactamases which effectively places it in a new class of antibiotics.

A broader spectrum than most antibiotics

The ability to resist destruction results in a greatly extended clinical spectrum. Zinacef's bactericidal effect extends to many pathogens, both Gram-positive and Gram-negative, resistant or partially resistant to established beta-lactam antibiotics.

[cefuroxime] '...is highly resistant to degradation by ß-lactamases.'
Richmond, M. H. & Wotton S., *Antimicrobial Agents and Chemotherapy* (1976) **10,** 219

With important therapeutic properties

- Zinacef has high bactericidal activity.
- Adequate serum levels are rapidly achieved and are well maintained.
- Zinacef is widely distributed with adequate levels in sputum, bile, bone and cerebrospinal fluid.
- Zinacef is not metabolised, but excreted, active and unchanged, in the urine.
- Zinacef has minimal toxicity, giving a wide margin of safety.
- Clinical trials have shown excellent renal tolerance.
- Zinacef can safely be used in neonates.
- Patient tolerance is excellent both intramuscularly and intravenously.
- Zinacef is compatible with commonly-used intravenous infusion fluids.
- There are no known clinically relevant adverse drug interactions.
- Zinacef can be used with other antibiotics to increase the antibacterial cover.

'…this wide antibacterial cover [illegible] [Zinacef] a useful antibiotic for the treatment of infections requiring prompt parenteral therapy before the causative pathogen has been identified.'
British Medical Journal (1978) **1**, 12[illegible]

ZINACEF

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 gram and infusion pack of 1·5 gram. All containing cefuroxime as cefuroxime sodium.

Indications
Serious bacterial infection, especially where the organisms have not yet been identified.
Conditions include:
Chest infections
Septicaemia
Soft tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Urinary tract infections
Ear, nose and throat infections
Meningitis
Gonorrhoea

Dosage
Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 gram t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary.
Infants and children: 30 to 100mg/kg/day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in two or three divided doses.
Gonorrhoea: Single dose of 1·5 gram (2 x 750mg i.m. into different sites).

Contra-indications
Hypersensitivity to cephalosporins.

Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria.
Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine.
As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage should be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.

Side effects
Adverse reactions are rare and generally mild and transient, e.g., rashes, gastro-intestinal disturbance, candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).

Storage
The powder in the infusion pack and vials should be stored below 25°C and protected from light.

Hollister conquers gas

At last-a highly effective flatus filter from Hollister

No leaks, no odour — Hollister have made sure that this new deodorising flatus filter is really effective and trouble-free.

Every colostomy patient knows the discomfort and embarrassment that occurs when a stoma bag swells up with flatus. Now Hollister have developed a flatus filter system that solves this problem successfully. Laboratory trials have proved its reliability.

Gas is released automatically through the unique Hollister* deodorising filter — packed with thousands of tiny odour-trapping granules of activated charcoal.

No leaky filter, no odour, no more discomfort or embarrassment. It really works. Hollister have conquered gas!

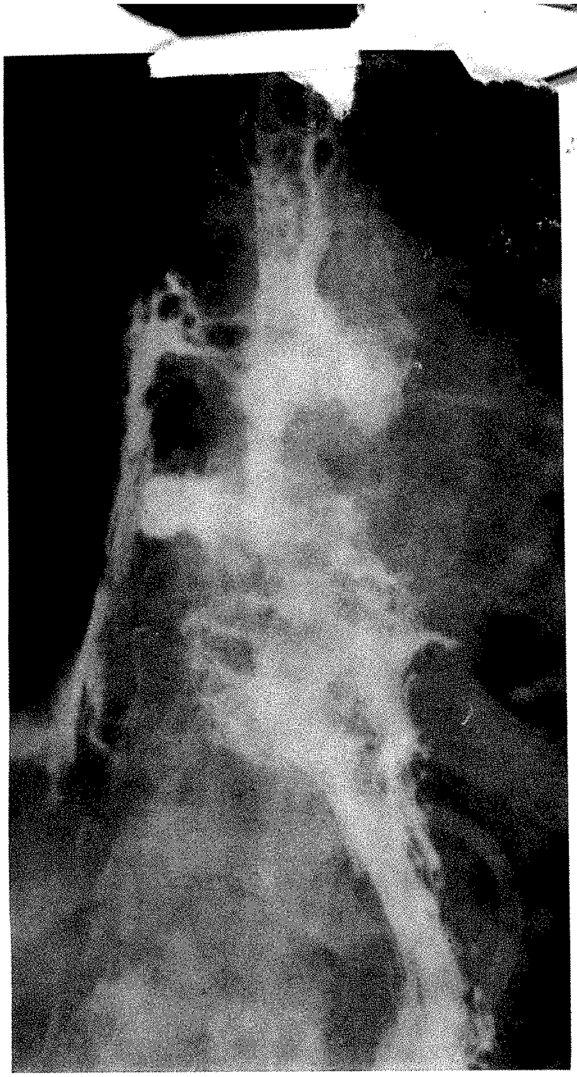

Fig. 2. (*Case* 1.) Radiograph showing leak from oesophago-gastroplasty.

tube drainage are performed through a small thoracotomy, on whichever side shows a hydropneumothorax, or into which pleural cavity there is extravasation of Gastrografin. The drainage tubes are placed next to the perforation to establish an oesophagocutaneous fistula and to drain the pleural cavity and mediastinum. Continuous suction is applied to the tubes through an underwater seal to ensure full expansion of the lung which will adhere to the parietal pleura around the tube and eliminate any space where air or fluid may persist to form an empyema (Froggatt and Gunning, 1966). This is the most important part of the treatment.

A gastrostomy is performed and the tube is connected to a Robert's suction pump to remove gastric secretions and/or any refluxed bile. This is especially important in low oesophageal tears where incompetence of the lower oesophageal sphincter causes persistent gastro-oesophageal reflux which is increased by the negative intrathoracic pressure.

The oesophagus is kept empty by suction applied to an indwelling naso-oesophageal tube or a T tube placed in a cervical oesophagostomy.

All patients are given tetracycline syrup and a fungicide by mouth so that a bolus of antibiotic reaches the most contaminated area. Wide spectrum systemic antibiotics are given during the acute stage of mediastinitis.

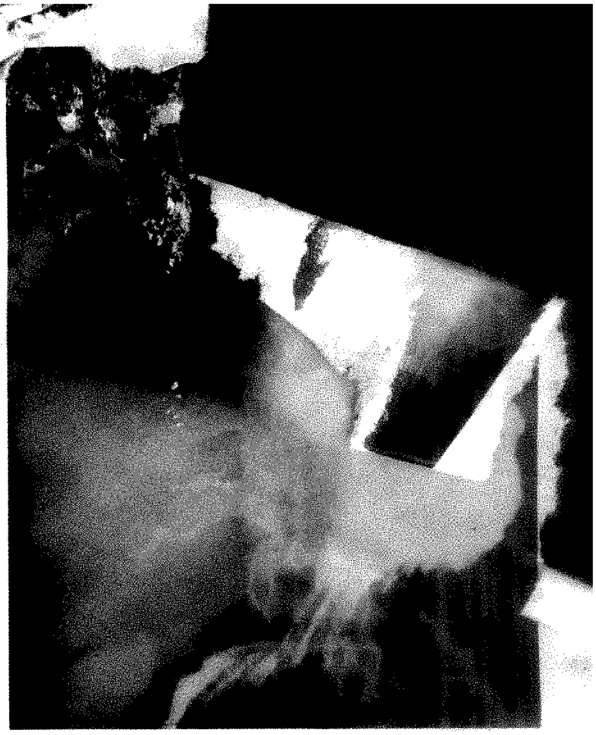

Fig. 3. (*Case* 1.) Gastrografin swallow showing healed perforation.

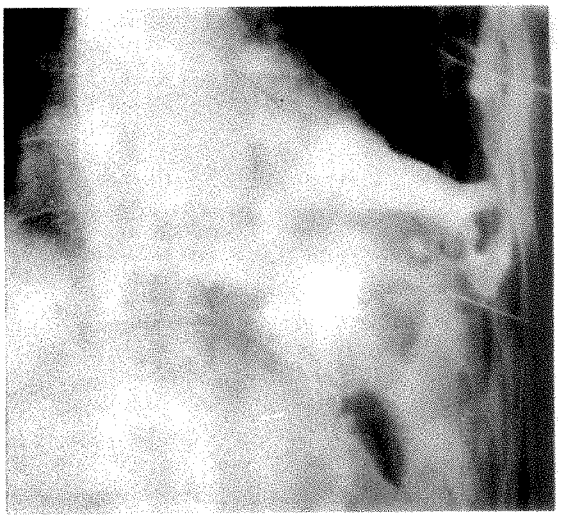

Fig. 4. (*Case* 2.) Gastrografin swallow showing leak from lower end of oesophagus.

Oral intake is stopped. These patients lose large amounts of protein and electrolyte-rich fluid which must be replaced in addition to the normal daily requirements of water, electrolytes, nutrients, vitamins and trace elements. The amounts to be replaced are achieved by keeping an accurate intake and output fluid chart which is reviewed every 24 h. Fluid and nutritional requirements are supplied by intravenous alimentation, the intravenous cannula being inserted into a subclavian vein by the infra- or supraclavicular route and changed every 7 days. Alternatively, jejunostomy feeding may be given through a tube introduced into the stomach and threaded

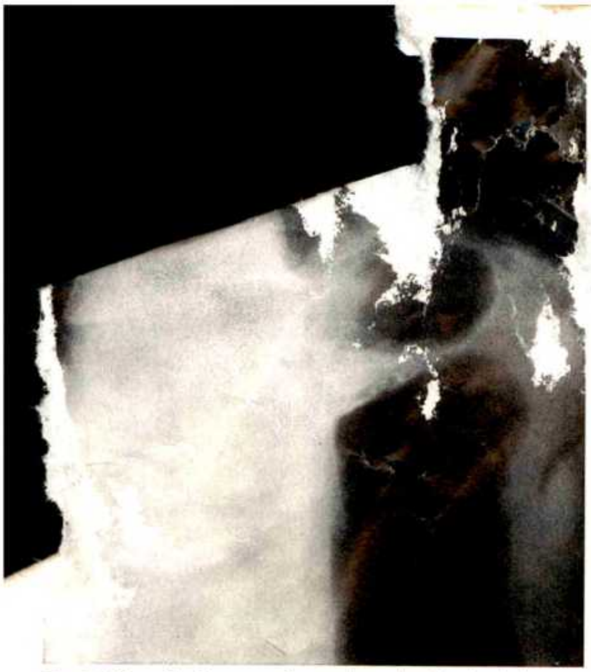

Fig. 5. (*Case* 2.) Gastrografin swallow showing healed perforation.

[illegible] into the jej [illegible] as the gastrostomy is performed.

Local treatment of the perforation by cauterization with 20 per cent sodium hydroxide is commenced at this time.

The patient is anaesthetized and the perforation visualized through a rigid oesophagoscope. Cotton wool pledgets are soaked in 20 per cent sodium hydroxide and then applied to the edges of the perforation with an applicator or forceps. Three or four applications are made of approximately 1 min duration. The sodium hydroxide is then neutralized with a 30 per cent solution of acetic acid. This procedure is repeated at weekly intervals until the perforation closes. Progress of closure is monitored by Gastrografin swallows (Froggatt and Gunning, 1966).

This method is illustrated in the following 5 case reports. There were no deaths. All the patients reported are now able to eat and drink without difficulty.

Case reports

Case 1: Mrs M. F., aged 49, underwent oesophagoplasty and a Nissen fundoplication (Nissen, 1956) for a congenital oesophageal stricture. A breakdown of the oesophageal suture line (*Fig.* 2) was diagnosed on the fifth postoperative day. The general measures described above were instituted and she was treated on the fourteenth postoperative day and twice thereafter with alkaline cauterization. The perforation healed (*Fig.* 3) and she was discharged 3 weeks later.

Case 2: Mr D. S., aged 43, presented with a 9-month history of dysphagia caused by achalasia of the cardia. A Heller's oesophagomyotomy was performed. Two days later a collection of fluid in the left pleural cavity and a small pneumothorax were shown to be present (*Fig.* 4). Three alkaline

of the oesophagus.
and one posterior in gus
the anterior and poste ars were sutured. A
placed around the lower end of the oesophagus and rvical
oesophagus drained by a T tube cervical oesophagostomy. This was done because at surgery it was felt that oesophageal replacement would be necessary. (*Fig*. 6 shows a Gastrografin swallow performed a week later and shows a persistent leak posteriorly.) This posterior tear required two alkaline cauterizations before closure. The ligature around the lower oesophagus was removed with some difficulty and the oesophagostomy closed spontaneously after removal of the T tube. He suffered no dysphagia and was able to eat normally (*Fig*. 7).

Case 4: Mrs E. D., aged 55, was another patient with spontaneous rupture of the oesophagus which occurred during an epileptic fit. She was moribund and was artificially ventilated for 2 weeks and was at first thought to have only a pneumothorax. A 4-cm oesophageal perforation at 30 cm was later diagnosed. She had weekly cauterization over a period of 2 months with gradual closure of the perforation. Her perforation healed, but she required decortication of an empyema cavity which developed due to inadequate drainage of the pleural cavity in the early stages and which we believe prolonged the closure of the perforation.

Case 5: Mr S. M., aged 71, developed a leak from the suture line after excision of a pharyngeal pouch which failed to close spontaneously. One alkaline cauterization resulted in closure of the perforation and he was able to swallow normally.

Discussion

A previous report from this unit (Froggatt and Gunning, 1966) advocated a relatively conservative approach for the treatment of chronic oesophageal perforations. However, in other centres more aggressive procedures have been adopted as the mortality associated with this 'drain and hope' method is said to be between 15 per cent and 50 per cent (Loop and Groves, 1970; Triggiani and Belsey, 1977).

This figure is too high (Leading Article, 1977) and can be drastically reduced by meticulous toilet and drainage of the mediastinum and pleural cavity in the first instance, followed by cauterization of the perforation with the local applications of sodium hydroxide to close the defect. This simple, but ingenious, technique was described by McCluskie (1975) and there is only one other report of its use (Agosti et al., 1978). Caustic irritation of the oesophageal mucosa

t the assertion that in
ation and transposition
of the fundus is critically
motic circulation involving
of the left gastric vessels, but
ese vessels can, if required, be
in most patients, provided that
e atherosclerosis. However, these
aat such a procedure may impair the
blooa the lesser curve, and they provide an anatomical explanation of the occasional occurrence of necrosis of the lesser curve following proximal gastric vagotomy.

In recent years the use of the mobilized stomach to replace the oesophagus in part, as in operations for carcinoma of the stomach (McKeown, 1976), or in its entirety, as in the treatment of post-cricoid carcinoma (Le Quesne and Ranger, 1966), has received increasing attention. In these operations all the vascular connections of the stomach are divided except for the right gastroepiploic and right gastric vessels; these are quite small, so that, in effect, the fundus of the stomach is dependent upon an anastomotic circulation stemming from the right gastroepiploic artery. According to McKeown (1976), the extragastric portions of the left gastric artery, lying along the lesser curve of the stomach, form an essential part of this anastomotic circulation, and hence must be preserved. However, Akiyama does not believe that these vessels play an important part in maintaining the viability of the fundus, and describes operations in which they are excised (Akiyama et al., 1976).

To clarify this problem a study has been carried out to determine whether, following the ligation of all the arteries to the stomach save only the right gastroepiploic, the viability of the fundus can be maintained solely by an intramural anastomotic circulation, or whether the extragastric arcade on the lesser curve is an essential component of the anastomotic supply to the fundus. In the event, the study also suggested an anatomical basis for the occurrence of lesser curve necrosis following the operation of proximal gastric vagotomy (highly selective vagotomy).

Materials and methods

Studies were carried out on 22 stomachs obtained at autopsy, 12 from men and 10 from women whose ages ranged from 19 to 90 years (average 67·5 years). Details concerning these subjects are set out in *Table I*. Specimens were not removed from subjects having gastrointestinal disease. Two injection techniques were used: the first used Chromopaque (Damancy and Co. Ltd) to obtain a two-dimensional picture of the region supplied by the cannulated vessel, and the second method employed a resin cast technique to define the exact pathway of the perfused vessels.

AUTOPSY SUBJECTS

22	M	64	Coronary thrombosis	140/80

Eight patients died from consequences of arteriosclerosis; 9 further patients had evidence of significant atheroma, of whom 2 had atheroma affecting the gastric vessels.

Chromopaque technique (18 stomachs)
In the course of a routine autopsy, each stomach was excised with its blood vessels intact, the short gastric vessels being divided close to the spleen. The oesophagus was divided 5 cm above the oesophagogastric junction and left open, whilst the duodenum was transected 2·5 cm beyond the pylorus and closed after washing out any stomach contents. The stomach was placed on a dissecting surface and the artery to be injected was identified throughout its course. All other vessels to the stomach were then dissected out, ligated flush with the stomach and divided. Cut omental edges were divided to prevent leakage of the injection material. A nylon intravenous cannula (Portex) of appropriate size was then inserted into the artery to be injected and the accompanying vein left open. In one stomach the cannula was placed in the right gastroepiploic artery, but the left gastric artery and its arcade on the lesser curve were preserved. In 15 stomachs the cannula was placed in the right gastroepiploic artery after removal of all other vessels and in the remaining 2 stomachs the cannula was placed in the main trunk of the left gastric artery, with removal of all other vessels (*Fig.* 1).

and (*c*) all the arteries to the stomach
the infusion, were removed after ligat
flush against the stomach wall.

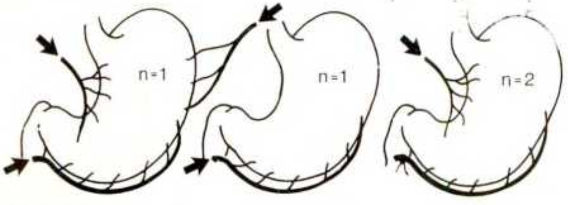

Fig. 2. Diagrammatic representation of the various infusions performed with resin. *See Fig.* 1 for explanation.

The stomach was next floated in a bath of 0·9 per cent saline solution and a small volume of air injected via the cannula to identify any leaks, which were sealed by further ligation. The nylon intravenous cannula was connected to the infusion apparatus for the injection of Chromopaque. The injection apparatus consisted of a pressurized bottle containing the injection medium, attached to a compressed air supply. The pressure within the system was maintained at 120–130 mmHg for a period of 3–6 min during the time of injection: this relatively high perfusion pressure was chosen to allow for the fact that many of the subjects were likely to have had systemic hypertension, as proved to be the case (*see Table I*). Injection was stopped when filling of the small serosal vessels was complete. After injection, the cannulated artery and the accompanying veins were ligated.

The intact stomach was then transferred to a Perspex board and a soft tissue radiograph taken using a Senographe CGR machine with CEA non-screen film and an exposure time of 1·5–1·7 s at 25 KV and 10 mA. After taking these films, the stomach was cut along the greater curve anterior to the epiploic arcade, except when the left gastric artery was injected, in which case the lesser curve was divided anterior to the left gastric arcade. The stomach was opened out and the serosal surface placed on the Perspex plate. Small vessel filling of the gastric mucosal vessels was assessed by naked eye examination and further X-rays were then taken.

In the two stomachs injected via the left gastric artery (*Fig.* 1*c*) the preparation was maintained at 37 °C during the injection of the Chromopaque medium, to which was added 10 per cent gelatin so that microangiography could be performed. After routine radiography, regions were selected for the microangiography. The selected area was arranged over a fine grain photographic plate (Ilford, EM5) and exposed by the same technique as above. The developed plates were then used to produce enlargements.

Resin cast technique (*4 stomachs*) (*Fig.* 2)

One stomach had a cannula placed in the right gastroepiploic artery, the left gastroepiploic artery and the left gastric artery with no ligation of vessels. Two stomachs had a cannula placed in the left gastric artery only, again with no ligation of other vessels while the remaining stomach had a cannula placed in the right gastroepiploic artery after removal of all other vessels. The stomachs were obtained and prepared for injection as already described. In some of the specimens the veins were also injected, with a different colour resin.

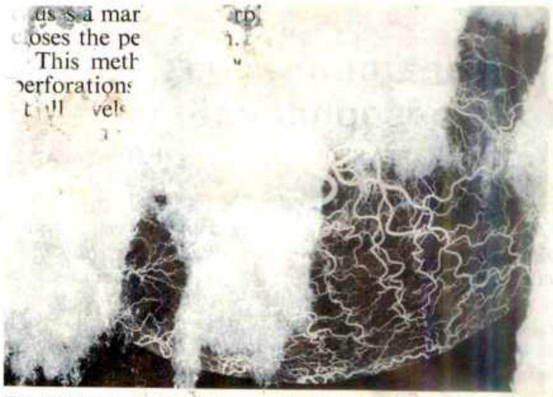

Fig. 3. Radiograph of a stomach following Chromopaqu
infusion via the right gastroepiploic artery (arrow) with
extragastric portion of the left gastric vessels intact (*Fi*
Note the good filling of the fundal vessels and also th
small calibre of the right gastric artery.

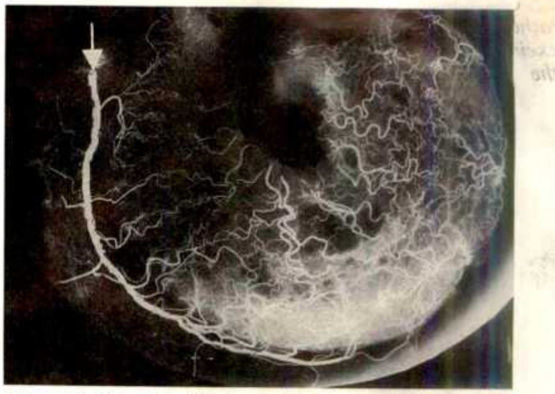

Fig. 4. Radiograph of a stomach following infusion via the right gastroepiploic artery (arrow), all the other gastric vessels having been removed (*Fig.* 1*b*). Note the good filling of the fundal vessels via intramural anastomotic channels.

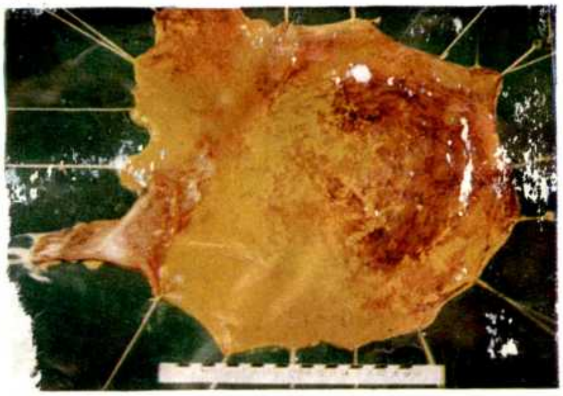
A cold-setting polyester resin (Trylon CL 201 PA) was injected using a modification of Tompsett's technique (Tompsett, 1970). The mixture of constituents (resin, monomer, catalyst and pigment) was made up just before injection while still cold from the refrigerator. During the perfusion the stomach floated in a saline bath at room temperature, but after the injection the saline bath temperature was raised to 40 °C to accelerate the setting process. Following either tissue maceration in concentrated hydrochloric acid or tissue clearing by dehydration and immersion in methyl salicylate, the vascular patterns were examined.

Results

When the three main arteries (left gastric, right and left gastroepiploic) were injected, there was, as expected, good filling of the fundal vessels. Similarly, injection of the right gastroepiploic artery with the left gastric arcade intact produced good filling of both the arcade and the fundal vessels (*Fig.* 3).

When the right gastroepiploic artery alone was perfused after ligation of all other vessels flush with the stomach, filling of the fundal vessels was obtained both with the Chromopaque and resin techniques (*Fig.* 4). In 14 of the 16 studies the filling of the fundal vessels was comparable with that seen after the injections when the left gastric artery was intact; the



5. A stomach opened along the anterior wall after
on of Chromopaque into the right gastroepiploic artery,
er vessels having been removed (*Fig.* 1*b*). The yellow
opaque has filled the vessels of the body and fundus,
ng a corridor of poorly perfused tissue (pink in the
re) along the lesser curve.

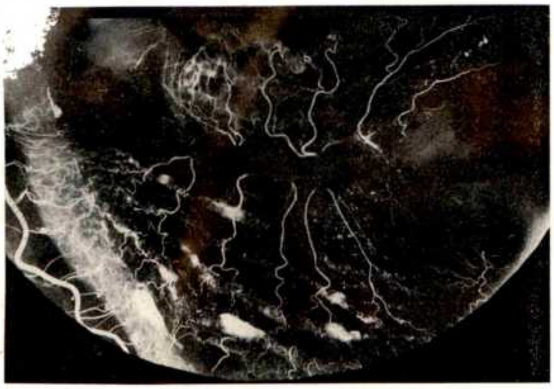


Fig. 6. Radiograph of a stomach opened along the greater curve after perfusion of Chromopaque via the right gastroepiploic artery (*Fig.* 1*b*). The avascular corridor along the lesser curve is clearly seen: this area of the stomach is supplied by the short branches of the left gastric artery, seen clearly in *Fig.* 8.

fundal vessels were seen to fill via the submucosal arterial plexus, although the lower oesophageal vessels undoubtedly filled better in the presence of the left gastric arcade. In the remaining 2 stomachs fundal filling was incomplete; in one this was due to technical errors and in the other there was marked atheroma of the main gastric arteries.

In the absence of the left gastric artery arcade the area least well filled was not the fundus of the stomach but the lesser curve of the stomach; this was true for all 16 stomachs examined in this manner. On opening the stomach, poor filling of the blood vessels of the lesser curve was obvious to the naked eye, leaving a corridor of poorly pigmented tissue, in sharp contrast to the yellow pigment easily seen in the body and, to a lesser extent, in the fundus of the stomach (*Fig.* 5). This avascular corridor along the lesser curve was also seen in radiographs of the opened stomach (*Fig.* 6). In those stomachs that were perfused via the left gastric artery after removal of all other vessels, no similar corridor was seen along the greater curvature.

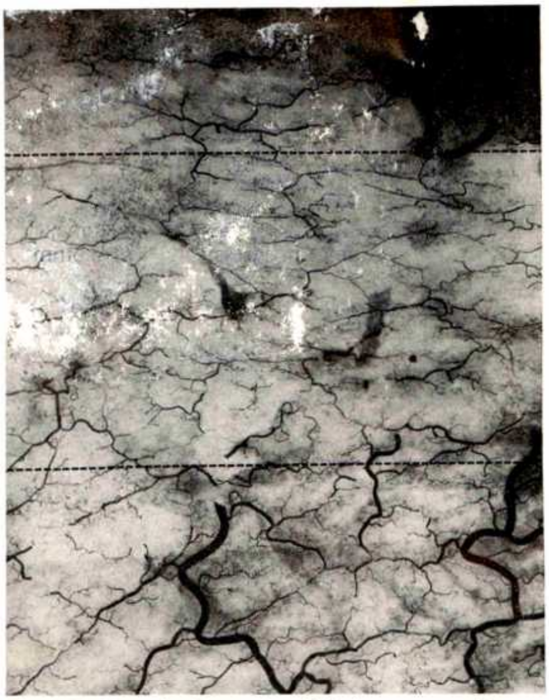

Fig. 7. Radiograph of a portion of the lesser curve of a stomach perfused with Chromopaque via the left gastric artery (*Fig.* 1*c*). The muscularis has been removed. The lesser curve lies across the centre of the picture, between the two dotted lines. On the anterior and posterior walls there is a free anastomosis between the submucosal vessels, whereas on the lesser curve anastomoses are fewer and end arteries are seen.

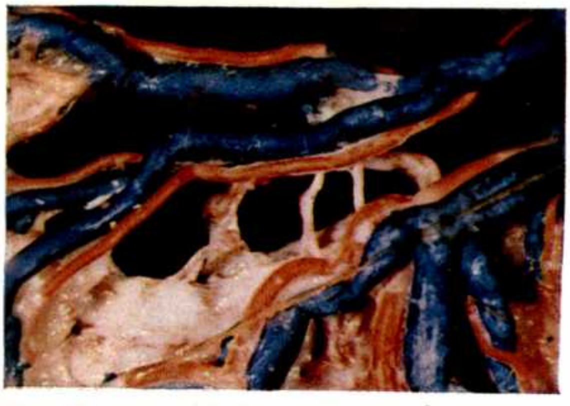

Fig. 8. Photograph of the lesser curve region of a stomach, after an infusion of resin into the left gastric artery (red) and vein (blue). The fat around the left gastric vessels together with the muscle coat of the stomach has been removed, to expose the submucous plane. In between the large branches running to the anterior and posterior walls of the stomach the smaller arteries running directly into the lesser curve can clearly be seen.

In order to examine the vascular pattern responsible for the corridor appearance on the lesser curve, areas of lesser curve were examined by microradiography and dissection. On the anterior and posterior walls there was a profuse anastomotic pattern of vessels fed from the main branches of the left gastric artery, while along the lesser curve itself a different pattern was apparent (*Fig.* 7). In this region the vessels were of smaller size, anastomoses were fewer and end arteries were noted, arising directly from the main branches of the left gastric artery and penetrating to the mucosa between the anterior and posterior leaves of the lesser omentum. These end arteries, which could be seen in the resin cast studies (*Fig.* 8), were present in the greatest numbers at the incisura angularis and became progressively less common proximally.

Discussion

In their meticulous study of the arterial supply of the human stomach, El-Eishi et al. (1973) clearly describe the distribution of the arteries supplying the stomach. But, whilst drawing attention to the many anastomoses in the gastric wall, they did not define the extent to which one artery could take over the territory normally supplied by another. This present investigation demonstrates that in an anatomical study the right gastroepiploic artery alone will perfuse the vessels in the fundus of the stomach, normally supplied by the left gastric artery. The perfusion of these vessels was found to be independent of the presence of the left gastric arcade and to occur through the submucosal anastomotic plexus. A feature of the injection pattern was the poor filling of the lesser curve vessels, which by microangiographic techniques was shown to be due to fewer intramural anastomoses.

Perfusion of the fundal vessels via the right gastroepiploic artery through the submucosal plexus has become important in the surgical management of oesophageal lesions with the realization that oesophagogastric anastomoses in the neck give rise to fewer and less dangerous problems than similar anastomoses in the thorax. Such an operation depends on the mobilization of the stomach into the neck without tension. It is currently recommended (McKeown, 1976) that the ligation of the left gastric artery at its origin is critical so that the gastric collateral branches are preserved, and the blood supply to the fundus secured. However, others have laid less emphasis on the integrity of the left gastric artery arcade (Akiyama et al., 1976). This study suggests that there is no anatomical basis for preservation of the left gastric arcade and that it can be removed without prejudice to the blood supply of the fundus of the stomach, provided that there is no significant atheroma of the right gastroepiploic artery. It should be noted, however, that an anatomical basis for fundal perfusion does not necessarily guarantee an adequate tissue blood flow. This purely *in vitro* study does not allow for the deformation and elongation which accompanies transposition of the stomach into the neck. However, the stomach is renowned for its ability to survive following ligation of many of its vessels, and it has been found that safety factors exist in the gastric circulation which allow a 60 per cent reduction in total gastric blood flow before an insufficiency of intracellular oxygen begins to limit cellular metabolism within the mucosa (Bowen et al., 1977). Thus, provided that the right gastroepiploic artery is not involved by atheromatous changes, it is likely that not only can this single vessel adequately perfuse the whole stomach, but that it can also do this in the absence of the extragastric arcade on the lesser curve. It is, however, to be noted that in the presence of severe atherosclerosis, transposition of the stomach may not be feasible even with the intact left gastric pedicle (Le Quesne and Ranger, 1966).

The end arteries noted on the lesser curve have been commented upon in previous studies on gastric vasculature (Reeves, 1920; Barlow et al., 1951; Piasecki, 1974), as has the decrease of the degree of anastomosis on the lesser curvature of the stomach (Piasecki, 1977). In no study, however, has the corridor effect been demonstrated after clearance of the lesser curve of the stomach. This area of poor filling is clearly related to the end arteries demonstrated in the resin casts and these arteries are sacrificed during proximal gastric vagotomy. This pattern of vascular supply probably explains the occasional occurrence of lesser curve necrosis following proximal gastric vagotomy (Johnston, 1975).

Acknowledgements

We are indebted to the late Professor R. D. Teare and Professor N. Woolf for allowing us access to the autopsy material on which this study was based. It is also a pleasure to express our thanks to the staff of the Department of Radiography and the Department of Physics for taking the radiographs, and to Mr R. Phillips and the staff of the Photographic Department for the illustrations.

When the dose of [illegible] secretagogues was reduced by 50 per cent, a [illegible] on day 0 prevented any changes occurring in the [illegible] denal mucosa, but when repeated at 4 weeks after a [illegible] the severity of duodenal ulcers in vagotomized rats [illegible] greater than in those having had a sham operation [illegible] 0·05). This transient effect of a PGV on duodenal ulcerogenesis and gastric secretion may be due to recovery of the parietal cell mass.*

PROXIMAL gastric vagotomy (PGV) is being performed more frequently in the surgical treatment of chronic duodenal ulcer in man (Johnston, 1975; Kennedy et al., 1975; Kronborg and Madsen, 1975; Jordan, 1976). The operation of PGV preserves vagal innervation to the antrum and pylorus allowing adequate gastric emptying without the need for a drainage procedure. In spite of a decreased morbidity and mortality after a PGV compared with other operations for duodenal ulcer, there is an increasing incidence of recurrent peptic ulceration with each year of follow-up (Wastell and Zervos, 1976). The possible reasons for this recurrent ulceration after a PGV include an incomplete or inadequate vagotomy, regeneration of the transected vagal nerve fibres or reinnervation of the parietal cells by cholinergic nerves from the antrum.

A method of producing duodenal ulcers in rats by the infusion of gastric secretagogues has been previously described (Joffe, Gaskin et al., 1977). These ulcers appear to be similar to the duodenal ulcers found in man both morphologically and in their natural history (Gaskin et al., 1976). They can be prevented by various gastric antisecretory agents (Joffe et al., 1976; Joffe, Polak et al., 1977) and truncal vagotomy (Joffe and Ferrie, 1976). The aim of this study was to see the effect of a PGV on experimental duodenal ulcers in the rat with emphasis on the gradual recovery of the parietal cell mass after a proximal gastric vagotomy.

Materials and methods

Male albino Wistar rats were deprived of food for 18 h before operation but allowed free access to water.

Operative technique

After anaesthetic induction with ether, a 2-cm midline abdominal incision was made from the xiphisternum. Using a ×8 magnification (Mediscope, Mark II), the stomach was delivered into the wound and the oesophagogastric junction and the anterior neurovascular bundle were exposed. This bundle contained the left anterior vagus nerve, which innervated the body and rumen of the stomach anteriorly as well as the antrum and pylorus. The nerve supplying the antrum and pylorus arose proximal to the oesophagogastric junction and was easily isolated.

P, pentagastrin (4 μg kg^{-1} min^{-1}); C, carbachol (0·8 μg kg^{-1} min^{-1}). PGV, proximal gastric vagotomy.

The posterior neurovascular bundle, which contained the right posterior vagus nerve, was exposed by reflecting the greater curvature of the stomach superiorly. Similarly, the vagal branch to the antrum arose above the oesophagogastric junction and could be easily isolated. These antral branches of the vagus in the rat are similar to the nerves of Latarjet which innervate the antrum in man, and these nerves can be clearly seen at the time of operation.

After identifying these vagal branches, two 5/0 silk ligatures were passed around the neurovascular trunks supplying the body and rumen anteriorly and posteriorly (*Fig.* 1). The neurovascular bundle was then divided between the ligatures and this denervated the body and rumen of the stomach but preserved the nerve supply to the antrum and pylorus. Haemostasis was achieved and the abdomen closed in layers using 2/0 silk for peritoneum and sheath and autoclips for skin. The sham operations consisted of laparotomy with identification and dissection of the vagal branches. The rats were weighed at 0900 h for 5 days preoperatively and then daily postoperatively. The animals were randomly allocated into two groups.

Group 1

A proximal gastric vagotomy was performed in 143 rats. Experiments were carried out on groups of rats immediately after operation and on each subsequent day until the tenth, and then again on the fourteenth and twenty-first days postoperatively. Using a Braun Unita I pump, a combination of two gastric secretagogues, pentagastrin (4 μg kg^{-1} min^{-1}) and carbachol (0·8 μg kg^{-1} min^{-1}) diluted to 18 ml with 150 mmol/l saline, was continuously infused subcutaneously into restrained rats for 24 h (Joffe, Gaskin et al., 1977).

On each of the postoperative days when the experiments were being performed, 3 sham and 3 unoperated rats were infused with gastric secretagogues and 3 unoperated rats were infused with saline, giving a total of 39 rats in each group (*Table I*). Immediately after the operation, and at 28 days postoperatively, a further group of 48 rats was infused with a 50 per cent dose of pentagastrin (2 μg kg^{-1} min^{-1}) and carbachol (0·4 μg kg^{-1} min^{-1}).

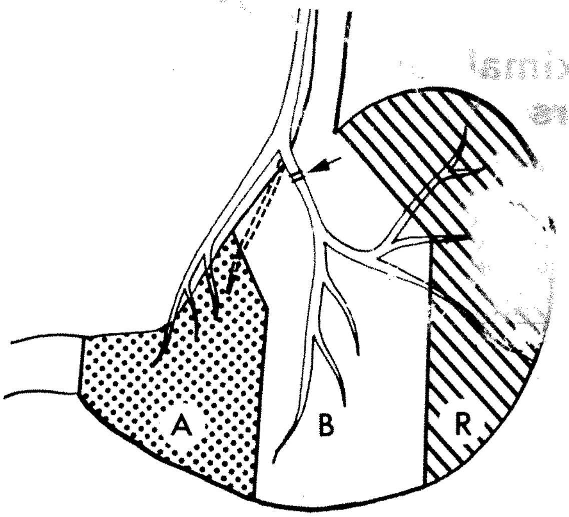

Fig. 1. Diagrammatic illustration of the trunk of the anterior vagus nerve dividing into the nerve to the antrum and pylorus (A) and the nerve to the rumen (R) and body of the stomach (B). The arrow represents the site of division of the branch of the anterior vagus nerve to the body and rumen of the stomach.

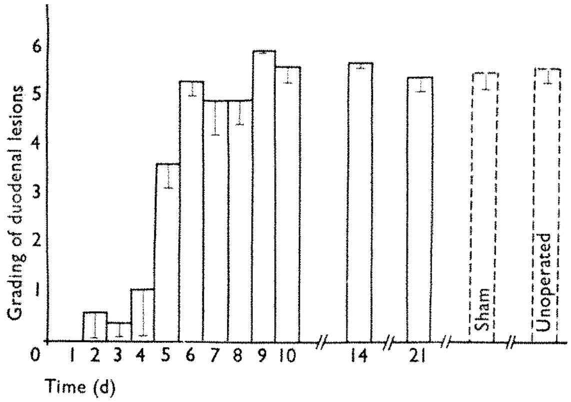

Fig. 2. Proximal gastric vagotomy and experimental duodenal ulcers: the influences of time after a proximal gastric vagotomy. The severity of duodenal lesions is graded semiquantitatively from 0 (normal) to 6 (penetrating or perforated duodenal ulcers).

At the end of the 24-h infusion the rats were killed using anaesthetic ether and a full laparotomy was carried out. The stomach and duodenum were opened along the greater curvature and antimesenteric surface respectively and then carefully inspected using a ×10 magnification lens for any duodenal lesion. The lesions were graded on a six-point scale of increasing severity by an observer who was unaware of the experimental conditions. Grade 0 was a normal mucosa, grade 1 oedema, grade 2 reddening of the mucosa, grade 3 petechiae, grade 4 erosions, grade 5 a definite ulcer crater and grade 6 penetrating or perforated duodenal ulcer.

Group 2

Gastric secretory tests were performed in sham-operated rats ($n = 30$) and PGV rats ($n = 30$) on day 0 and on the seventh postoperative day using a gastrostomy tube sutured into the rumen of the stomach for aspiration of the gastric contents (Joffe, Polak et al., 1977). The gastric juice was collected at 15-min intervals by gentle suction into 5-ml syringes and the volume measured. Following a 1-h basal period, pentagastrin (4 μg kg^{-1} min^{-1}) and carbachol (0·8 μg kg^{-1} min^{-1}) were subcutaneously infused and the gastric juice collected for a further 4 h. At the end of the 5-h experiment the acidity was determined by titrating against 0·1 N NaOH with phenol red as an indicator. The total acid output was expressed in μmol/60 min. Statistical analysis was carried out using Student's *t* test and the Mann–Whitney U test.

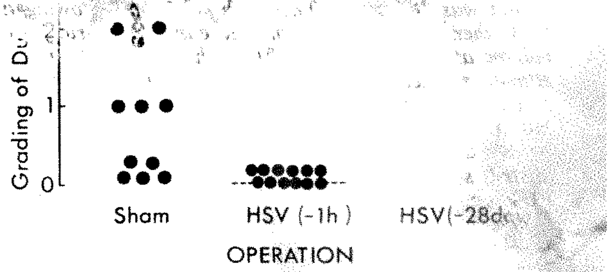

Fig. 3. The severity of duodenal lesions produced by a 24-h subcutaneous infusion of the gastric secretagogues pentagastrin (2 μg kg^{-1} min^{-1}) and carbachol (0·4 μg kg^{-1} min^{-1}) in sham-operated rats, immediately on recovery from a proximal gastric vagotomy (1 h) and 28 days after the PGV. The severity of duodenal lesions is graded from 0 (normal) to 6 (penetrating or perforated duodenal ulcers).

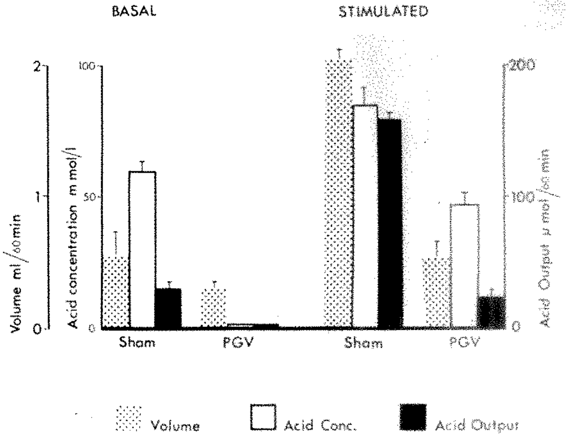

Fig. 4. Gastric secretory tests in rats after a sham-operation and immediately on recovery after a proximal gastric vagotomy (PGV) on day 0 (volume in ml/60 min, acid concentration in mmol/l and total acid output in μmol/60 min). Both basal and stimulated acid output after pentagastrin (4 μg kg^{-1} min^{-1}) with carbachol (0·8 μg kg^{-1} min^{-1}) are shown.

Results

During this study none of the rats died. The mucosa of the stomach and duodenum in unoperated rats and

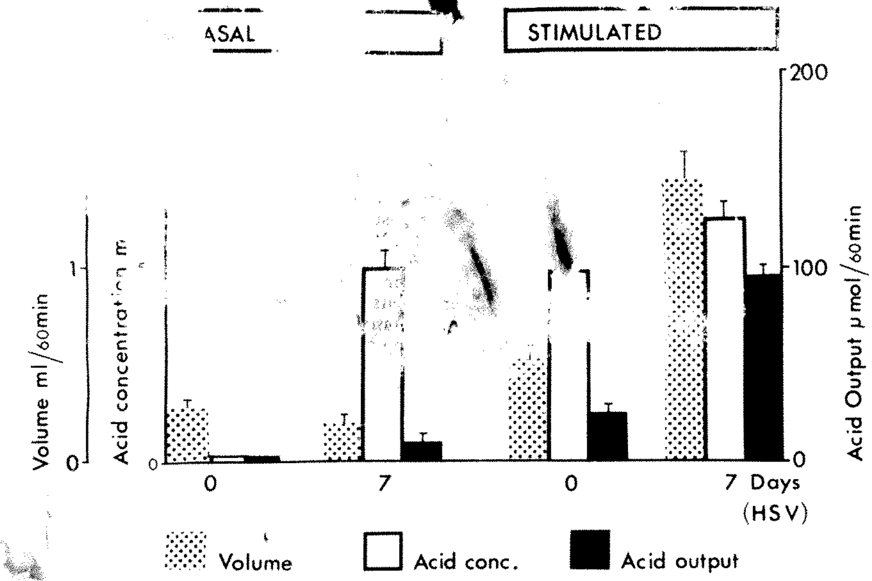

Fig. 5. Gastric secretory tests in rats immediately on recovery after a proximal gastric vagotomy on day 0 and 7 days postoperatively (volume in ml/60 min, acid concentration in mmol/l and total acid output in µmol/60 min). Both basal and stimulated acid output after pentagastrin (4 µg kg^{-1} min^{-1}) with carbachol (0·8 µg kg^{-1} min^{-1}) are shown.

in PGV rats after a 24-h infusion of saline was normal (grade 0). Pentagastrin and carbachol produced a 100 per cent incidence of duodenal ulceration in sham-operated and unoperated rats. The effect of the gastric secretagogues in vagotomized rats is shown in *Fig.* 2. Pentagastrin and carbachol had virtually no effect on the duodenal mucosa from day 0 to day 3 after a PGV. However, on day 4 there was evidence of a penetrating duodenal ulcer in 1 of the 8 rats infused with the gastric secretagogues. The remaining rats had a normal duodenal mucosa. By day 5, 3 out of 8 rats had a duodenal ulcer and this secretagogue-induced duodenal ulceration was consistently present on days 7, 8, 9, 10, 14 and 21 after a PGV (*Fig.* 2).

When rats were subcutaneously infused with 50 per cent of the ulcerogenic dose of gastric secretagogues for 24 h, sham-operated rats developed a wide range of changes in the duodenal mucosa. This varied from being macroscopically normal to duodenal ulceration with perforation. The mean severity of the duodenal lesions in this group was 2·6 (*Fig.* 3). A proximal gastric vagotomy followed immediately on recovery by an infusion of this half-dose of gastric secretagogues totally prevented any changes in the duodenal mucosa (grade 0). However, when the same experiments were repeated 4 weeks after a PGV, there was a significant increase in the duodenal lesions produced ($P<0{\cdot}05$) and all the rats developed either duodenal erosions ($n = 3$) or duodenal ulcers ($n = 9$) (*Fig.* 3).

In sham-operated saline-infused rats the mean BAO was 33 µmol/60 min and after secretagogue stimulation the BAO was significantly increased to a mean of 186 µmol/60 min ($P<0{\cdot}001$). After recovery from a proximal gastric vagotomy (day 0), the basal volume of gastric juice was 0·27 ml/60 min and the fluid was achlorhydric. On stimulation with gastric secretagogues, there was an increase in these PGV rats in both volume and acidity and acid output increased to a mean of 12 µmol/60 min (*Fig.* 4).

In the PGV rats on day 7 there was a significant increase in gastric juice volume after secretagogue stimulation ($P<0{\cdot}001$) and in acidity ($P<0{\cdot}001$) of the gastric juice when compared with the early postoperative results (*Fig.* 5). The gastric secretory tests performed in the sham-operated rats 1 week postoperatively did not differ significantly from the results obtained immediately after operation ($P>0{\cdot}1$).

Discussion

In this study a proximal gastric vagotomy has been shown to have a temporary inhibitory effect on experimental duodenal ulcers. From the sixth postoperative day all the rats developed duodenal ulcers after a subcutaneous infusion of ulcerogenic doses of gastric secretagogues regardless of the PGV. There are several possible explanations for this change in responsiveness of the gastric parietal cells to the infusion of pentagastrin and carbachol.

The recurrent peptic ulceration in man and the increase in acid output with time in response to insulin seen after a proximal gastric vagotomy may be due to vagal nerve regeneration or 'sprouting'. The changes found in these animal experiments, however, occurred too early in the postoperative period for this process to have occurred. Furthermore, histological staining of nerve tissue and electron microscopy of gastric mucosa from rats undergoing a truncal vagotomy shows nerve degeneration of the vagal fibres innervating the parietal cells on postoperative days 4, 7, and 11 (Kalabanis et al., 1974).

If the formation of duodenal ulcers in unoperated or sham-operated rats is due to the combined actions of pentagastrin, carbachol and a normal vagal tone, then in vagotomized rats the total stimulus to acid secretion would be less. Initially, the reduced stimulus would be inadequate to produce duodenal ulceration. With the recovery of the parietal cell sensitivity, however, the reduced stimulus becomes adequate, causing the peptic ulceration. The increase in both the basal and stimulated gastric acid output on the seventh postoperative day would tend to support this. The duodenal lesions produced by infusing half the dose of gastric secretagogues over 24 h also indicated a change in the responsiveness of the gastric parietal cells. On day 28 following a PGV all the rats developed either duodenal erosions or ulceration compared with the duodenal changes in sham-operated rats (grade 2·6) or the normal duodenal mucosa found in rats after a PGV followed immediately by an infusion of a 50 per cent dose of gastric secretagogues. The supposition that there is an early return of gastric secretory cell sensitivity after vagal denervation seems defensible.

An alternative hypothesis is that the duodenal ulceration is due entirely to the pentagastrin and carbachol administered and that vagotomy inhibits for several days the effect of these gastric secretagogues. This mechanism involves assumptions for which there is no collaborative evidence. In view of the period of decreased sensitivity to stimulation being so brief, it may well be a non-specific effect of the operation rather than a direct consequence of the vagotomy. The stimulant regimen might be so powerful as to be unaffected by vagotomy and the transient postoperative insensitivity could be due to ischaemia resulting from the inevitable devascularization of the proximal stomach during the vagotomy.

There have been several reports indicating a change in responsiveness of the parietal cell to stimulation after a proximal gastric vagotomy, without any adequate explanation for the effect. Amdrup and Griffith carried out experiments in dogs with Heidenhain pouches 3–4 weeks after a PGV (Amdrup and Griffith, 1970). Although there was no change in the fasting Heidenhain pouch secretion, there was a significant rise in the 24-h gastric output in response to food. Hirschowitz et al. (1976) also found changes in cholinergic receptors in dogs after a proximal gastric vagotomy.

It is entirely possible that the effect of the operation is due to ischaemia resulting from the inevitable devascularization which occurs during the PGV. Further work is necessary to determine the more precise caus[illegible] rec[illegible] of the secreto[illegible] in the stoma[illegible] afte[illegible] [illegible]mal gast[illegible]

[illegible] pyloroplasty for gastric ulcers

[illegible] D M. [illegible] AR*

[illegible] gas[illegible] [illegible]ated by [illegible] a dis[illegible] general hospital [illegible] were re[illegible] postoperative deaths in the patien[illegible] surgery but 8 deaths in those [illegible] emergency surgery for massive bleedin[illegible]). Eighty-three per cent of patients had a [illegible] was classed as good or satisfactory. Recurrent gastric ulceration was found in 8 per cent and a tendency to late asymptomatic ulcer recurrence is identified. Careful long term follow-up, including endoscopic re-examination, is advocated for patients undergoing conservative operations for benign gastric ulcer.

In recent years there has been a move towards less radical surgery in many fields. In keeping with this trend and encouraged by previous experience and enthusiastic reports (Farris and Smith, 1963; Dorton, [illegible]: Hendry and Bahrani, 1965; Burge, 1966; Kraft et al., 1966; McNeil et al., 1969; Burge et al., 1970; Daniels and Strachan, 1973), 80 patients with proved benign chronic gastric ulcers have been treated by vagotomy and pyloroplasty in a district general hospital. This study reports the results of those operations.

Patients and methods,

The records of all 80 patients with benign gastric ulcers treated surgically by vagotomy and pyloroplasty during the period January 1971 to November 1975 in a district general hospital were reviewed. There were 60 surviving patients of whom 44 were personally interviewed by one author (M. C. E.). Information was obtained from general practitioners on a further 9 and 7 were lost to follow-up.

At interview, each patient's symptoms were graded according to a modified Visick scale (Duthie et al., 1970). A routine follow-up endoscopic examination was planned in all cases but this was contraindicated in 9 asymptomatic patients on medical grounds or because of age. Hence, 35 patients were invited to attend for a follow-up endoscopic examination and 28 of these accepted. These examinations were carried out as outpatient procedures by one author (M. C. E.) and included gastric mucosal biopsy in all cases.

Three-quarters of the patients in this study were under the care of one of the authors (M. W. L. G.) and in most of these cases a standard management protocol was followed, which included a preoperative endoscopic examination with tissue sampling for both cytological and histological assessment, an operative biopsy of the gastric ulcer for frozen section and also subsequent paraffin section histology, and, finally, a postoperative endoscopic examination several months later. The remaining patients were under the care of two other consultant general surgeons and no single management protocol was used in these cases.

Table I shows the extent to which the standard protocol was followed. The surgery involved truncal vagotomy in 46 cases and selective vagotomy in the other 34. The pyloroplasty was of the Heinicke–Mickulicz type in all cases.

The cases were subdivided into groups representing the three types of gastric ulcer—type I gastric ulcer, type II combined gastric and duodenal ulcer and type III prepyloric gastric ulcer (Johnson, 1965)—based on the site of the ulcer and the presence or absence of duodenal ulceration as shown on endoscopic and/or operative findings.

The recurrence rate and symptomatic results were assessed for each type of gastric ulcer separately. All results were tested for significance using the exact test for 2×2 contingency tables (Bailey, 1959).

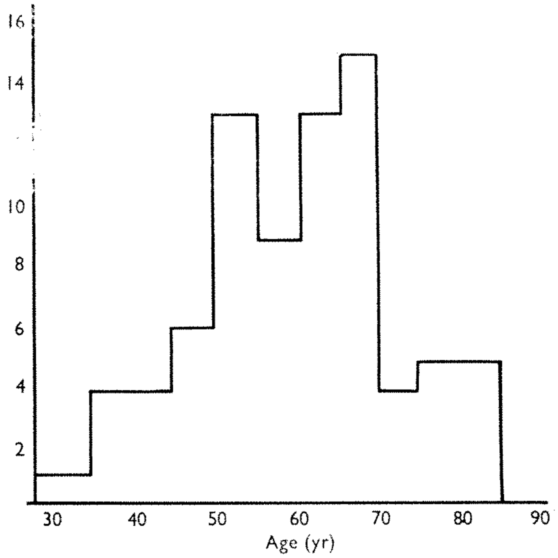

Fig. 1. Age distribution of 80 patients in this study.

Results

The study consists of 80 patients—49 male and 31 female—with an age distribution as shown in *Fig.* 1. In 59 patients surgery was undertaken electively for the standard surgical indications. There were no postoperative deaths in this group. The remaining 21 patients were operated on for massive or continuing bleeding and there were 8 postoperative deaths (38 per cent) in this group.

The patients were subdivided according to the type of gastric ulcer and *Table II* shows the numbers in each group. Twenty patients have died since surgery from a variety of causes, as shown on *Table III*, and a further 7 were lost to follow-up. The remaining 53 have all been followed for at least 2 years, with an average follow-up of 4·2 years. Sixteen of the 18 patients operated on 5 or more years ago had complete follow-up information. *Table IV* shows the modified Visick grading for those 54 patients with adequate follow-up. This group included 44 patients having elective surgery and 10 patients having emergency surgery for bleeding. Seventy-four per cent of this group had a good result (Visick 1 and 2), 9 per cent a satisfactory result (Visick 3) and 17 per cent a poor result (Visick 4 and 5). *Table V* shows the modified Visick grading in those 44 patients having elective surgery. A good result was achieved in 79·5 per cent, a satisfactory result in 4·5 per cent and a poor result in 16 per cent. These results do not differ significantly from those obtained after emergency surgery.

Tables IV and *V* also show the modified Visick grading when the patients are subdivided according to ulcer type. There were no significant differences in

For total parenteral nutrition, Travenol makes SYNTHAMIN, amino acid injections, in three concentrations with and without a balanced electrolyte profile. A further concentration is available with an energy substrate.

To complement this range of solutions, Travenol provides specialized "V" and "W" administration sets, and both central and peripheral venous catheters.

Travenol also supplies the means for compounding TPN regimens in the pharmacy, using VIAFLEX plastic containers for non-air-dependent administration.

All Travenol products are supported by comprehensive technical back-up and an extensive in-service organization.

Synthamin amino acid injections

Presentation
Synthamin injections are sterile, non-pyrogenic solutions of essential and non-essential L-amino acids, provided with or without electrolytes. Synthamin 7S also provides carbohydrate as Sorbitol.

Indications
Parenteral nutrition.

Dosage and Administration
Dosage depends on patient's metabolic requirement and clinical response. For intravenous administration an assimilable source of non-protein energy should be administered of not less than 0.75MJ (180Kcal) per gram of nitrogen administered.

Contraindications
Severe liver disease. Solutions with electrolytes are contraindicated in renal failure.

Precautions
As with all hypertonic solutions, vein irritation may occur.

Availability
Synthamin 7S (PL0116/0043)
500ml £4.20 1000ml £7.56
Synthamin 9 (PL0116/0054)
500ml £5.15
Synthamin 9 (PL0116/0087)
500ml £4.80 without electrolytes.
Synthamin 14 (PL0116/0055)
500ml £7.35
Synthamin 14 (PL0116/0088)
500ml £7.00 without electrolytes.
Synthamin 17 (PL0116/0056)
500ml £8.90
Synthamin 17 (PL0116/0089)
500ml £8.55 without electrolytes.

Full prescribing information is available from Marketing Services Department.

PULSE VOLUME RECORDER (PVR®)*

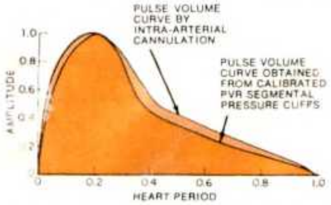
The NON-INVASIVE Clinical Vascular Laboratory

An Extensively Documented Clinical Procedure for the Quantitative Evaluation of Peripheral Vascular Disease:

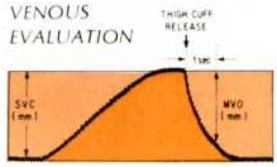
Arterial — Venous — Cerebral

Excellent Long-term Reproducibility and Calibrated Accuracy by Quantitative Segmental Cuff Technique

Ophthalmic artery pressure is read directly on the OPG Attachment of the PVR for the evaluation of collateral circulation to each eye, and its respective cerebral hemisphere.



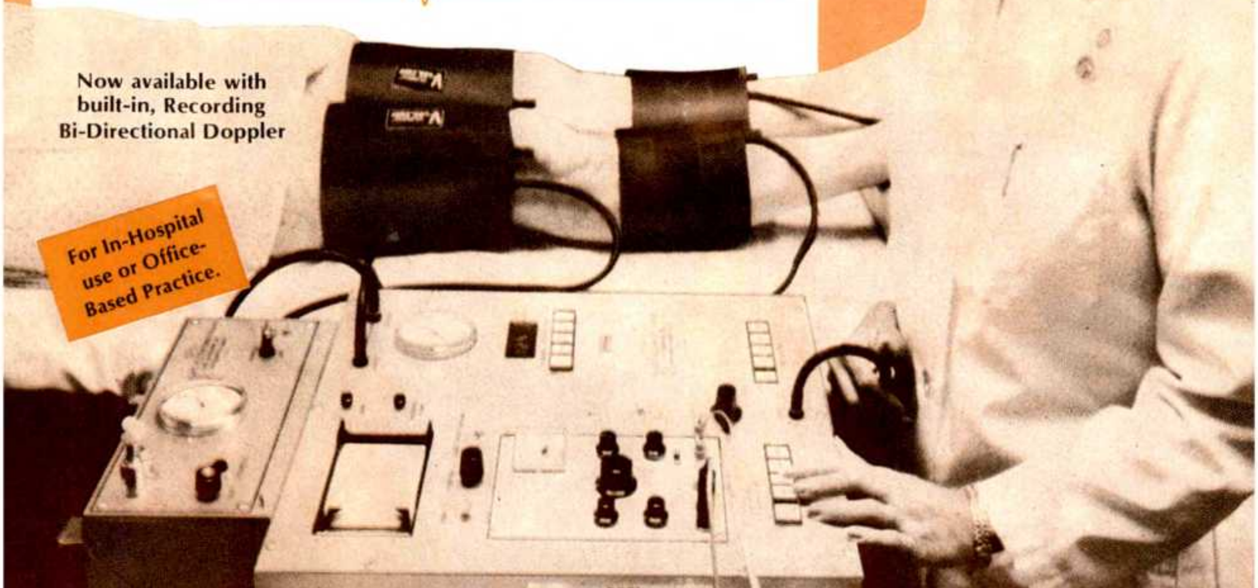
Comparison of pressure contours obtained with the PVR and direct cannulation of the common femoral artery.



A 15-point scale provides approximately 5% false (+) and 2% false (-).

Total Segmental Perfusion (primary vessel plus collaterals) is accurately documented at the thigh-calf-ankle-metatarsal level and digits. The built-in Doppler facilitates the measurement of pressures along the arterial tree.

The COMBINED information of segmental PVR recordings and systolic pressure gradient establishes a clinically accurate picture of functional perfusion.



Now available with built-in, Recording Bi-Directional Doppler

For In-Hospital use or Office-Based Practice.

Visick grading or ulcer recurrence between type I [illegible] types II and III gastric ulcers.

Table VI shows the modified Visick grading befo[illegible] endoscopic examination for all 44 patients interview[illegible] divided according to whether or not they had an endoscopic examination. The 16 patients who were not examined all had a good (Visick 1 and 2) or satisfactory (Visick 3) result. Of the remaining 28 patients, 71·5 per cent had a good result, 18 per cent a satisfactory result and 10·5 per cent a poor result. The difference between these two groups was not statistically significant. The 9 poor results represent 4 recurrent gastric ulcers proved at endoscopy, 1 recurrent gastric ulcer proved at post-mortem, 1 patient requiring reoperation for obstruction and 3 patients with severe post-vagotomy symptoms.

Three cases of extensive gastric carcinoma presented at 2 years 7 months, 2 years 11 months and 3 years 3 months respectively after surgery. A fourth case of peritoneal carcinomatosis of undetermined primary site presented at 6 years after surgery. There was 1 case of 'ulcer-cancer' and 1 case of an incidental finding of leiomyoblastoma of the stomach.

Discussion

The accepted standard surgical treatment for benign gastric ulcer is Billroth I gastrectomy. This operation has given good results but is by no means ideal (Louw and Marks, 1977). The operative mortality may be low in specialized units but the accepted world mortality rate is of the order of 2 per cent (Baron and Spencer, 1976; Johnston and Goligher, 1976) and may reach 4–5 per cent even in good units (Louw and Marks, 1977). The reported recurrence rate is at least 2 per cent and may reach 4–6 per cent (Johnson and Judd, 1971; Duthie and Kwong, 1973; Neilsen et al., 1973). There is also a significant minority of patients who develop substantial post-gastrectomy syndromes.

The lower operative mortality of vagotomy and drainage of about 1 per cent (Baron and Spencer, 1976; Johnston and Goligher, 1976) and its proved ability to heal gastric ulcers (Dragstedt et al., 1944; Farris and Smith, 1963; McNeil et al., 1969; Burge et al., 1970; Duthie et al., 1970) have led a number of surgeons to use this operation in the surgical treatment of benign gastric ulcers. The reports of this treatment have ranged from enthusiastic (Burge, 1966) to pessimistic (Stemmer et al., 1968). Many series have reported a low operative mortality, a recurrence rate after surgery of about 5 per cent and symptomatic results comparable to those obtained with Billroth I gastrectomy (Burge et al., 1970; Clarke et al., 1972; Kennedy et al., 1972; Johnston and Goligher, 1976).

These results prompted Duthie and co-workers to report a controlled prospective trial of vagotomy and pyloroplasty versus Billroth I gastrectomy in the surgical treatment of benign gastric ulcers. They found a recurrence rate of 10 per cent after vagotomy and pyloroplasty and 4 per cent after Billroth I gastrectomy (Duthie and Kwong, 1973). There were no operative deaths in either group but significantly greater operative morbidity occurred after Billroth I gastrectomy. This was partly offset by an early symptomatic superiority of gastrectomy (Duthie et al., 1970) which, however, was not maintained with longer follow-up (Duthie and Kwong, 1973). These authors concluded that vagotomy and pyloroplasty was a satisfactory operation for gastric ulcer when there were reasons for avoiding gastrectomy, but their trial produced no evidence that vagotomy and pyloroplasty should replace gastrectomy as the operation of choice.

All figures are percentages.

The situation is much less controversial when emergency surgery for a bleeding gastric ulcer is conside [illegible] Several authors have reported mortality rates [illegible] vagotomy and pyloroplasty with under-running [illegible] the bleeding vessel which are approximately half thos[illegible] obtained with emergency gastrectomy (Esselstyn, 1976; Johnston and Goligher, 1976), yet with no significant differences in rebleeding rates (Esselstyn, 1976). The results in this study are very much in accord with the preceding ones. There were no operative deaths among the 59 patients having elective operations, but there were a disturbing 8 deaths among the 21 having emergency operations for bleeding (38 per cent). There were 5 proved recurrent gastric ulcers in the 65 patients who have been fully followed up (8 per cent). The modified Visick grading of symptoms of 54 patients (*Table IV*) showed that 74 per cent had a good result, 9 per cent were satisfactory and 17 per cent poor. These results include 10 patients who had emergency surgery for massive blood loss but the results are not significantly different if these emergency cases are excluded (*Table V*).

Several authors (Kennedy et al., 1972; Duthie and Kwong, 1973; Douglas and Duthie, 1971) have reported much better results when vagotomy and drainage is used to treat type II and III gastric ulcers than when it is used to treat type I ulcers. Duthie believes the inclusion of type II and III gastric ulcers in studies of gastric ulcers treated by vagotomy and pyloroplasty favourably biases the results of surgery and he feels this may explain some of the wide variations in the results. However, we have not been able to confirm this in our study. There were 4 recurrent ulcers in 50 type I gastric ulcers (8 per cent), with 72 per cent having a good symptomatic result, and 1 recurrence in 15 type II and III gastric ulcers (7 per cent), with 80 per cent having a good symptomatic result. These differences are not significant.

One gastric ulcer recurred 13 months after surgery but the remaining 4 recurrent ulcers all presented 5 or more years later. This gave a recurrence rate of 22 per cent in the 18 patients operated on at least 5 years ago. This feature of late recurrence has been observed by other authors (Stemmer et al., 1968). They reported 5 recurrent ulcers in 18 patients (36 per cent) treated by vagotomy and drainage presenting at a mean of 5·2 years after surgery.

In the present study the striking feature of these late recurrent ulcers was the virtual absence of symptoms. Two patients were entirely asymptomatic and were found to have recurrent ulcers at follow-up endoscopy, 1 patient had vague abdominal discomfort which was not suggestive of recurrent ulceration and the fourth presented with a massive gastrointestinal bleed having had no premonitory symptoms. Four of these 5 patients with recurrent ulcers were re-examined endoscopically a few months after their original operation and in all cases the original gastric ulcer was seen to have healed. It is of interest that 28 patients in this series agreed to endoscopic re-examination and 3 recurrent gastric ulcers were found, all in patients who had had their operation at least 5 years previously.

These late asymptomatic recurrent ulcers indicate that careful follow-up of patients, including endoscopic re-examination, is necessary. Ideally these patients should be re-examined at yearly intervals, but this poses considerable practical problems. In addition to any logistic problems, there is the difficulty [illegible]f long term follow-up in a continually ageing popula[illegible]on. In this study a routine endoscopic re-examina[illegible]n was considered to be contraindicated in asympto[illegible]ic patients over 75 years of age and in those with [illegible]cal conditions such as recent ischaemic chest pain. [illegible]asonable compromise would be to follow all [illegible] annually in the outpatients department and [illegible]ne endoscopically those developing symptoms [illegible] haemoglobin concentration.

[illegible]udy 3 patients presented with extensive [illegible]r at a mean of 2 years 11 months after [illegible]ll have subsequently died. A further [illegible]ed with peritoneal carcinomatosis of un[illegible]ed primary site 6 years later. Three of these 4 patients had preoperative and operative tissue sampling without evidence of malignancy and postoperative endoscopic examination confirmed healing of the gastric ulcer.

The absence of any evidence of malignancy on tissue sampling, the observed healing of the ulcer and the time interval of well over 2 years between surgical treatment of the original ulcer and the presentation with gastric cancer suggest that these cases represent 'new' rather than 'missed' cancers.

There was one case of true 'ulcer-cancer'; this man had a microscopic focus of malignancy within a benign gastric ulcer. This was detected on paraffin section histology having been overlooked on frozen section histology. He had a Polya gastrectomy and has remained well without recurrent tumour. This case serves to illustrate that conservative surgery for gastric ulcers must be undertaken with great care to avoid missing potentially curable ulcer-cancers. The use of endoscopic examination including tissue sampling for both histological and cytological assessment has achieved a high but not complete level of accuracy (Gear and Rocyn-Jones, 1977). In this study there were two instances of endoscopic biopsy material reported as containing malignant tissue and two reports of malignant cells seen in cytological specimens, yet in each case no evidence of malignancy was detected at operation or on an operative specimen. All 4 patients have since remained well for an average of 4 years. This reinforces the need to obtain adequate operative biopsy specimens to confirm an endoscopic diagnosis. No cases of early gastric cancer were detected in the 28 follow-up endoscopic examinations. In all cases multiple gastric mucosal biopsies were taken and it is planned to report the mucosal changes detected in a subsequent paper.

In conclusion, this study confirms that there will be a 'good' or 'satisfactory' result in over 80 per cent of patients with benign gastric ulcer treated by vagotomy and pyloroplasty. However, the number of asymptomatic late recurrent ulcers raises the question about the long term efficacy of the operation. It appears from this study and previous reports that this operation is particularly indicated in those patients with type II and III ulcers; it should also be used when there are reasons for avoiding a gastrectomy, such as a potentially technically hazardous operation in a frail patient or in one with a substantial risk of postgastrectomy syndrome and as emergency surgery for a bleeding ulcer. The tendency towards late, asymptomatic ulcer recurrence and the cases developing gastric cancers reported in this study raises a note of caution and implies a prolonged follow-up period with endoscopic re-examination where appropriate. The results of current trials using highly selective vagotomy in the treatment of benign gastric ulcer are awaited with interest.

Appendix

Statistical method

All results in this paper were analysed by compiling 2 × 2 contingency tables. The exact probability of each observed result was calculated using the following formula (Bailey, 1959).

a	b	$a+b$
c	d	$c+d$
$a+c$	$b+d$	n

$$P = \frac{(a+b)! \times (c+d)!\,(b+d)!\,(a\times c)!}{n!\,a!\,b!\,c!\,d!}$$

Results

Comparison of Visick grading between elective and emergency care:

	Poor (Visick 4+5)	Good or satisfactory (Visick 1+2+3)	
Elective operations	7	37	44
Emergency operations	2	8	10
	9	45	54

$P > 0{\cdot}32$.

Comparison of Visick grading between type I and type II+III ulcers having elective surgery:

	Poor	Good or satisfactory	
Type I ulcer	5	26	31
Type II+III ulcers	2	11	13
	7	37	44

$P > 0{\cdot}35$.

Comparison of Visick grading between those patients having an endoscopic examination and those not:

Lipid meta[illegible]nd nitrogen balance aft[illegible] abdominal [illegible] in man

K. J. FOSTER, K. [illegible]LBERTI, C. BINDER, L. HINKS, S. [illegible] KARRAN,
H. ØRSKOV, F. S[illegible] TAL[illegible]OT AND D. TURNELL*

SUMMARY

The relation of lipid metabo[illegible] nitrogen balance was studied in patients having [illegible]rgo[illegible] abdominal surgery and was compared wit[illegible]rol [illegible]jects who [illegible]d fasted for a similar perio[illegible] [illegible]tie[illegible]s had lower [illegible]culating concentrations [illegible] glyc[illegible]ol, [illegible]on-esterified [illegible]ty acids and ketone bodies. T[illegible]ere were inverse [illegible]relations between blood alanine and ketone body [illegible]centrations in both patients ($r = -0{\cdot}64, P<0{\cdot}01$) [illegible] *controls* ($r = -0{\cdot}58, P<0{\cdot}01$). *Nitrogen excretion [illegible]tients (1[illegible] 7 mmol/kg body weight/day ± 1·4 s.e. was greater than by controls* ($9{\cdot}2$ mmol kg^{-1} [illegible] $0{\cdot}8, P<0{\cdot}05$), *but a more marked difference was [illegible]ed for urinary methyl histidine excretion of* $5{\cdot}1 \pm 0{\cdot}5$ [illegible] $kg^{-1} d^{-1}$ *by patients and only* $2{\cdot}5 \pm 0{\cdot}3$ µmol kg^{-1} [illegible]$^{-1}$ *by controls* ($P<0{\cdot}01$), *a disparity indicative of more active protein turnover after surgery.*

THE accelerated rate of nitrogen loss from the body after surgical operation or injury remains a matter of concern, especially when patients are unable to eat for protracted periods. Small amounts of glucose, about 0·55 mol (100 g) daily, can, however, decrease nitrogen loss in otherwise starving subjects (Gamble, 1946).

Infusion of ketone bodies into fasting obese subjects also causes a decrease in nitrogen excretion, and a decrease in blood alanine concentration in normal fasting subjects (Sherwin et al., 1975). Alanine has a key role in metabolism, being formed and released by muscle in quantities much exceeding its content in muscle and accounting for half the gluconeogenic substrate derived from amino acids (Felig, 1973). Blood ketone body concentrations increase remarkably during starvation in normal and obese subjects and become a predominant source of fuel. Gluconeogenesis from amino acids decreases after the first few days of starvation and this, with perhaps a direct inhibitory effect of ketones on muscle breakdown, may contribute to protein conservation (Cahill, 1976).

The absence of large increases in blood ketone body concentrations in certain seriously infected or injured patients suggests impaired ketogenesis, which may, with other metabolic and hormonal changes, contribute to the accelerated nitrogen loss (O'Donnell et al., 1976). Changes in levels of blood ketone bodies and other intermediary metabolites have not been fully investigated following surgical operations in completely starved patients. We have therefore compared the metabolic changes seen in patients after elective surgery with those observed in normal fasting volunteers.

Patients and methods

Six patients undergoing elective abdominal surgery were studied from the first to fourth postoperative day. None had significant endocrine, renal, hepatic or cardiorespiratory dysfunction, none was on concomitant drug therapy and none had postoperative complications. Anaesthesia was induced with intravenous thiopen[illegible]e and suxamethonium and maintained with halothane [illegible] nitrous oxide, tubocurarine being used as a muscle r[illegible]xant. Papaveratum and pr[illegible]xazine or metaclopramide were used in the early postoperative period to control pain or vomiting. From the start of the operation until 9 a.m. on day 1 patients received 2–3 l of 4·3 per cent (0·24 mol/l) glucose—0·18 per cent (0·03 mol/l) sodium chloride solution supplying 0·48–0·72 mol (86–129 g) glucose. Subsequently, they received 2–3 l/d 0·9 per cent (0·15 mol/l) saline with 27 mmol/l (2 g) potassium chloride. All patients were mobilized out of bed as much as possible from day 1.

Five healthy non-obese volunteers fasted for a similar period, that is from 10 p.m. the night before the equivalent to operation day (day 0). They took 0·27 mol (50 g) glucose orally at 9 p.m. on day 0 and at 7 a.m. on day 1. At other times they took only water by mouth and remained sedentary.

Estimations of ideal body weight were made (Metropolitan Life Insurance Co., 1959) and fat-free mass was assessed by measuring skinfold thicknesses (Durnin and Womersley, 1974) on each subject.

Fifteen-millilitre samples of free-flowing antecubital venous blood were taken after the subjects had rested supine for 1 h at 9 a.m. daily and at 9 p.m. on day 1. Blood, deproteinized immediately in 5 per cent (v/v) perchloric acid was centrifuged and the supernatant used for automated fluorimetric assay of glucose, alanine, lactate, glycerol and 3-hydroxybutyrate (Lloyd et al., 1978) and spectrophotometric assay of acetoacetate (Price et al., 1977). Plasma was used for assay of non-esterified fatty acids (NEFA) by a modification of the method of Ho and Meng (1969) and routine measurement of electrolytes. Serum insulin was measured by a double antibody method (Soeldner and Slone, 1965). Rapid centrifugation of 2·5 ml of blood taken into tubes containing 2500 i.u. aprotinin and 2·5 µmol Na EDTA gave plasma for assay of glucagon by a wick chromatography method (Ørskov et al., 1968). Serum cortisol was measured by a competitive protein binding technique (Kehlet et al., 1974).

Three consecutive 24-h urine collections were made from 9 a.m. on day 1 using 25 ml 5 N hydrochloric acid as preservative. Total urinary nitrogen excretion was measured by the micro-Kjeldahl technique and urinary 3-methylhistidine excretion was assessed with a Technicon TSM amino acid analyser using a lithium citrate buffer system.

Statistical comparisons were made using paired and unpaired Student's *t* tests.

Results

The fasting volunteers were younger than the surgical patients but in other respects the two groups were similar (*Table I*). Metabolite concentrations at 9 a.m. on days 0, 2 and 4 are shown in *Table II*. Before operation serum insulin was higher ($P<0{\cdot}05$) in the control subjects, but the concentrations of this and

Table III: MEAN±S.E. MEAN URINE TOTAL NITROGEN AND 3-METHYLHISTIDINE EXCRETION IN THE FIRST 3 DAYS AFTER ABDOMINAL OPERATION IN 6 TOTALLY STARVED PATIENTS AND IN 5 HEALTHY VOLUNTEERS UNDERGOING A COMPARABLE PERIOD OF FASTING

	Patients	Fasting volunteers
Urine total nitrogen excretion (mmol kg^{-1} d^{-1})	12·7±1·4	9·2±0·8*
Urine 3-methylhistidine excretion (μmol kg^{-1} d^{-1})	5·1±0·5	2 5±0·3**

Significant difference between groups, * $P<0·05$, ** $P<0·01$.

other parameters were within the normal reference range after an overnight fast for this laboratory (Foster et al., 1978).

Glucose and alanine

Blood glucose concentration fell in both groups during the study, but was significantly higher in the surgical patients. Blood alanine concentration fell in both groups, insignificantly in the control subjects but in the patient group alanine concentration on day 4 was significantly less than before operation ($P<0·05$) and significantly less than in the fasting volunteers ($P<0·05$). There was a significant inverse correlation of alanine with ketone bodies in the patient ($r=-0·64$; $P<0·01$) and control groups ($r=-0·58$, $P<0·01$).

Lipid metabolites

There was a rise in all lipid metabolite concentrations in the fasting volunteers (*Table II*). In particular, ketone body (3-hydroxybutyrate plus acetoacetate) concentration in the volunteers rose to 5·68±0·12 mmol/l by day 4, but to only 2·94±0·41 mmol/l ($P<0·001$) in the patients. Within the patient group on day 4, ketone body concentrations were generally highest in the eldest patients. On day 4 the youngest patient (male, 41 years) had a blood ketone body concentration of 1·90 mmol/l compared with 5·86 mmol/l in the oldest control (male, 35 years).

Hormones

During the period of complete fasting, serum immunoreactive insulin concentration fell to low and similar values in each group. Plasma glucagon rose significantly in both groups but remained elevated on day 4 only in the control group. There was a significant rise in serum cortisol concentration after operation and at 9 p.m. on day 1 serum cortisol in patients (523±111 nmol/l) was higher than in the fasting volunteers (231±35 nmol/l, $P<0·05$).

Electrolytes

There were no changes in the plasma sodium or potassium concentration in either group but plasma bicarbonate fell during the study from 27±1 mmol/l to 20±1 mmol/l in the volunteers ($P<0·01$) and from 26±1 mmol/l to 22±1 mmol/l in the patients ($P<0·01$). The volunteers had a mean urinary sodium loss of 71 mmol/d whereas the patients whose mean intake was 269 mmol/d had a positive balance of 125 mmol/d, exclusive of cutaneous losses. Mean urinary potassium loss by the volunteers was 34 mmol/d whereas patients who received a mean of 48 mmol potassium/d had a net loss of 22 mmol/d.

Nitrogen excretion (*Table III*)

Mean urinary nitrogen excretion in the 3-day study period was 9·2 mmol kg^{-1} d^{-1} by the volunteers and 12·7 mmol kg^{-1} d^{-1} by the patients ($P<0·05$). The mean urinary 3-methylhistidine excretion by control subjects was 2·5 μmol kg^{-1} d^{-1}, also lower than that by the patients (5·1 μmol kg^{-1} d^{-1}, $P<0·01$). No significant correlations between lipid metabolites or hormones and nitrogen excretions were observed except for plasma glucagon and urine nitrogen in patients ($r = 0·71$, $P<0·01$) and controls ($r = 0·54$, $P<0·05$).

Discussion

Starvation is known to result in a fall in blood glucose and insulin and a rise in lipid metabolites (Cahill et al., 1966). Similarly, blood alanine concentrations fall (Felig et al., 1969) and glucagon rises in the early phases of starvation (Aguilar Parada et al., 1969). These changes were observed in both our fasted controls and postoperative patients, but the extent of these physiological changes was smaller in the surgical patients. As expected, blood glucose and nitrogen excretion increased after operation. In association with lower blood alanine concentrations after operation, this implies increased hepatic extraction of alanine for gluconeogenesis and ureagenesis in the early postoperative period. This may account for the correlation of glucagon with urine nitrogen since glucagon appears to have little effect on protein metabolism outside the liver (Fitzpatrick et al., 1977). The similarity in serum insulin in the two groups, despite higher blood glucose concentration after operation, suggests inhibition of secretion of insulin, perhaps similar to that noted in the peroperative period (Allison et al., 1967).

The mean nitrogen excretion can be calculated to be equivalent to a loss of 170 g amino acid by a 70-kg control subject in the 3-day study period and of 235 g amino acid by a 70-kg patient, an excess of 65 g after operation. 3-Methylhistidine is an amino acid which is found in particularly high concentration in muscle and which is excreted unchanged and not reincorporated into muscle after breakdown (Long et al., 1975). Its excretion is thus a useful marker of muscle protein turnover, which probably accounts for half of total body protein turnover (Long et al., 1977). Assuming a content of 3-methylhistidine in human muscle of 1·76 mol/g dry weight (Asatoor and Armstrong, 1967), approximately 300 g dry muscle protein was broken down by the controls in the 3-day study period and 600 g by the patients. The disparity between these losses and that calculated from nitrogen excretion indicates considerable protein synthesis from amino acids released from muscle by both groups, but particularly by the postoperative patients. Previous workers have noted increased 3-methylhistidine excretion in some severely injured subjects (Williamson et al., 1977).

Studies on protein turnover after surgery using isotopically labelled amino acids showed similar rates of breakdown in controls and patients but slightly depressed rates of protein synthesis postoperatively (O'Keefe et al., 1974; Crane et al., 1977). Such isotope studies consider whole body turnover just as urinary nitrogen represents whole body net protein breakdown, but the disparity with our results is surprising.

Our patients were found to have depressed circulating concentrations of NEFA and particularly of ketone bodies, with inverse correlations between blood ketone bodies and alanine in both groups. *In vitro* ketone bodies have been observed to decrease alanine release from isolated muscle (Palaiologis and Felig, 1976). The lower ketone body concentration in the patient may in part account for the observed increase in muscle protein breakdown. However, blood alanine concentration fell more quickly in the patients, which also implies both a change in the normal ketone body/alanine relationship and increased hepatic amino acid extraction.

Glycerol is released by adipose tissue on hydrolysis of triglyceride and is taken up by the liver at a rate dependent upon its concentration (Shaw et al., 1976). The lower glycerol concentrations in the patients suggest that lipolysis was stimulated less after operation than during simple starvation. The metabolic rate is known to change little after operation (Kinney, 1967) and therefore the depressed ketone body levels are probably due to decreased production rather than increased extraction. Ketone body production is in part related to NEFA concentration (McGarry and Foster, 1972). Both lipolysis and ketogenesis are well known to be very readily inhibited by small concentrations of insulin, which is probably the main regulatory mechanism for these processes. Serum insulin concentrations were similar in both groups and the relative impairment in lipolysis and ketogenesis postoperatively is unexplained. Glucagon has ketogenic properties, but these are relatively weak and ineffective in the presence of even low concentrations of insulin (Schade and Eaton, 1975). Our findings on lipid metabolism are surprising since cortisol (for which we noted both a rise in concentration and a loss of diurnal variation after operation) and particularly catecholamines (for which rises in concentration during and after operation have previously been described [Nikki et al., 1972]) have lipolytic actions. Nevertheless, a comparable finding of an inverse relationship of ketone body concentration after orthopaedic injury to the severity of injury despite similar insulin concentrations in the more and less severely injured, has already been reported (Williamson and Smith, 1979).

It is likely that the differences noted between patients and controls were the result of operation itself. Halothane anaesthesia causes little metabolic disturbance (Oyama and Takazawa, 1971) and postoperative medication was not required in the latter part of the study. As expected, the patients were in positive sodium balance, whereas, again as expected, the control subjects were in negative sodium balance (Boulter et al., 1974). It seems unlikely that these factors could account for the marked differences noted. The patients received a small amount of glucose intravenously before the test period, and the controls a similar amount orally. The route of administration of glucose does not alter its effect on nitrogen balance (Fitzpatrick et al., 1975) and would appear unlikely to affect metabolic parameters 24–72 h later. The patients were older, but this is unlikely to have caused the observed differences. After an overnight fast blood ketones and NEFA concentrations are higher in older subjects (Foster et al., 1978) and during the study ketone body concentrations tended to rise more in the older patients. Nitrogen turnover is decreased in the elderly (Golden and Waterlow, 1977) so that the differences in ketone body and nitrogen metabolism we observed [illegible] have been more marked had we had controls of similar age to the patients.

Comparison of brush cytology before or a[illegible] biopsy for diagnosis of gastric carcinoma*

M. R. B. KEIGHLEY, H. THOMPSON, JANET MOORE, A. M. HOARE, R. N. ALLAN AND P. W. DYKES†

SUMMARY

A randomized trial has compared the res[illegible] of brush cytology before or after biopsy in patients [illegible] solitary gastric lesions. One hundred and eleven carcinomas were identified in 324 patients. False positive histological reports were recorded in 2 patients but there were no false positive cytology results. The cumulative accuracy of biopsy and cytology in patients with carcinoma was 97 per cent, which was significantly better than biopsy a[illegible] (83 per cent, $P<0{\cdot}001$) or cytology alone (87 per cent, $P<0{\cdot}001$). The cumulative results of brushing before biopsy were significantly better than results obtained by brushing after biopsy ($P<0{\cdot}05$) and indicate that brush cytology should normally be performed before biopsy.

THERE is a wide variation in the reported accuracy of endoscopic biopsy (Kobayashi et al., 1970) and brush cytology (Hermanek, 1973) in the diagnosis of gastric carcinoma. The benefit of obtaining both cytological and histological material has already been emphasized (Witzel et al., 1976). Although most investigators prefer to brush before biopsy, it has been suggested that if gastric lesions are brushed first, the accuracy of subsequent biopsy may be reduced (Smithies et al., 1975). To investigate this hypothesis we have undertaken a prospective randomized trial of brush cytology before or after biopsy amongst patients with solitary gastric lesions attending for elective endoscopy.

Patients and methods

Patients with solitary gastric lesions seen on elective upper gastrointestinal endoscopy at the General Hospital or Queen Elizabeth Hospital, Birmingham, between January 1975 and October 1977, entered the trial. Only patients who had a barium meal before endoscopy were admitted for study. Instructions on numbered randomization cards indicated whether the lesion should be brushed before or after biopsy. Of the 347 patients who were included in the study, 23 were withdrawn either because they had had a previous endoscopy and had therefore been entered twice or because of failure to attend for clinical or endoscopic review.

Endoscopy was performed by four clinicians using the Olympus GIFD or GIFK endoscope. At least four biopsies were obtained using the ACM (American Cystoscope Manufacturers) Martin biopsy forceps with a bayonet needle (catalogue number 70354). Material was collected for cytology by vigorous brushing of the lesion with a non-disposable nylon brush. Cases of carcinoma were excluded unless the diagnosis had been confirmed by operation, repeat endoscopy or autopsy. Patients with benign disease were excluded unless they attended for a repeat endoscopy (usually 6 weeks) or were reviewed at follow-up for at least 6 months or until symptom-free.

The histological material was examined in the pathology department by any member of the university staff, whereas the cytological smears were reported by one person (H. T.). The material obtained by gastric brushing was smeared on to a glass slide and fixed immediately in alcohol. The smear was stained using the Papanicolaou technique. Of the patients who completed the trial, brushing was performed before biopsy in 161 patients and after biopsy in 163 patients.

Table I: OVERALL RESULTS

	Carcinoma ($n=111$)	Non-malignant ($n=213$)
Positive histology alone	92 (83%)	2 (1%)
Positive cytology alone	96 (87%)	0
One or other technique, positive	106 (97%)***	2 (1%)

*** $P<0{\cdot}001$ compared with histology alone or cytology alone.

Table II: RESULTS OF THE TRIAL

	Positive histology	Positive cytology	One or other technique positive
Brush before			
Carcinoma ($n=57$)	47 (82%)	52 (91%)	57 (100%)
Non-malignant ($n=104$)	0	0	0
Total errors	10	5	0
Brush after			
Carcinoma ($n=54$)	45 (83%)	44 (82%)	49* (91%)
Non-malignant ($n=109$)	2	0	2
Total errors	11	10	7**

* $P<0{\cdot}05$ compared with cumulative accuracy of brush cytology before biopsy.
** $P<0{\cdot}01$ compared with total number of errors using brush cytology before biopsy.

Results

A final diagnosis of carcinoma was recorded in 111 patients. In 15 cases the tumour involved the oesophagus but only 5 were squamous cell lesions. There were 2 patients with early gastric carcinoma.

The accuracy of biopsy in patients with gastric carcinoma (83 per cent) was inferior to the accuracy of cytology alone (87 per cent); however, this difference was not statistically significant (*Table I*). When the cumulative accuracy of a positive pathological diagnosis from one or other technique was calculated (97 per cent) this was found to be significantly better than either cytology alone ($\chi^2 = 12{\cdot}3$, $P<0{\cdot}001$) or histology alone ($\chi^2 = 10{\cdot}0$, $P<0{\cdot}001$). There were two false positive histology reports. Both were in patients with gastric ulcer who subsequently underwent gastrectomy and the final diagnosis in the resected specimen indicated that both lesions were benign. By contrast, there were no false positive cytological findings.

The results of the trial (*Table II*) have indicated that the cumulative accuracy of cancer diagnosis was significantly better when brush cytology was performed before biopsy (100 per cent) as compared with the results of brushing after biopsy (91 per cent) ($\chi^2 = 5{\cdot}3$,

---

* This work was presented in part at the Surgical Research Society in January 1979.

† The General and Queen Elizabeth Hospitals, Birmingham.

$P<0{\cdot}05$). This difference was due to a reduction in the accuracy of brush cytology from 91 per cent when the lesion was brushed first and only 82 per cent when brushing was performed after biopsy. The total number of errors was significantly less when brushing was performed first ($P<0{\cdot}01$).

Discussion

The results of this trial indicate that, provided an experienced cytological service is available, brush cytology should always be performed as well as biopsy. The cumulative results were significantly better than either procedure taken in isolation. Our cumulative accuracy was as good as the results obtained from multiple biopsies, a technique which is extremely time-consuming for the endoscopist as well as for the histopathology department (Dekker and Tytgat, 1977). Using both criteria, only 5 patients with cancer were missed at the first endoscopic examination. One of these patients was lost to follow-up and returned with a haematemesis 6 months later. All other patients were thought to have a carcinoma from the macroscopic appearance of the tumour and the repeat endoscopic examination confirmed the lesion to be malignant. None of the other patients with non-malignant biopsies or brush cytology had clinical or endoscopic evidence of gastric carcinoma during follow-up.

The accuracy of biopsy diagnosis in this study is not as good as in most other reports, the average value for an accurate histological diagnosis being 87 per cent (Hermanek, 1973). However, our biopsies were reported by all members of the histopathology department. Although all the biopsy specimens were later reviewed by one person, it was felt that the results of this study should be analysed according to the initial reports. When the histology was reviewed, both false positives were considered to be non-malignant but only one of the false negative reports was changed. The results of the initial reports indicate normal hospital practice rather than the artificial situation of a single person's interpretation of the biopsies, which never reflects the accuracy outside a clinical trial (Segal et al., 1975). By contrast, cytological material from both the hospitals in this study is always reported by one person and we felt that there was no justification for changing this practice during the trial. It is encouraging that we were able to record no false positive cytological reports, which is in marked contrast to the experience of other units (Sherlock et al., 1972; Weidenhiller, 1974).

Our results have also shown that brushing does not impair the accuracy of subsequent biopsy since the accuracy of histology in both groups was the same. However, the accuracy of brush cytology was less reliable when biopsies had been performed first, indicating that biopsy may make interpretation of brush cytology difficult. Furthermore, it is often difficult to localize the site of malignancy if biopsy has caused bleeding. When brushing was performed before biopsy there were no false positive results and the diagnosis of carcinoma was never missed using both diagnostic methods. When brushing was performed after biopsy there were 2 false positive reports and 5 cases of carcinoma were missed by both methods (7 errors). This difference is statistically significant and indicates that brush cytology should normally be performed before biopsy.

Spontaneous an[illegible]natic rupture of hepatoma

NAOFUMI NAGASUE AN[illegible]HI INOKUCHI*

SUMMARY

Hepatoma is a common cause of spontaneous rupture of the liver. During recent years, spontaneous rupture was found in 11 (7 per cent) of 157 patients with hepatoma. The rupture occurred spontaneously in [illegible] patients, traumatically in 1 while in 3 patients trivial trauma seemed to be the precipitating factor. A correct preoperative diagnosis was made in 7 patients, all of whom were known to have a hepatoma. Hepatic resection was performed in 4 patients, 2 of whom were long-term survivors. Haemorrhage stopped in 2 of 3 patients who underwent hepatic artery ligation, but only 1 patient was discharged from hospital. The remaining patients, who were treated by packing, suture or laparotomy alone, died within a short time after admission. It is suggested that resection is the preferred management, but if this is not possible hepatic artery ligation should be performed.

PRIMARY carcinoma of the liver is a challenging disease, because it is difficult to diagnose and may present management problems. One such problem is rupture of the carcinoma with intraperitoneal bleeding. This complication is rare in Caucasians (MacDonald, 1957; El-Domeiri et al., 1971; Kew et al., 1971), but is more frequent among Chinese (Ong et al., 1965; Kuo et al., 1970) and South Africans (Alpert et al., 1969). In the English literature there are many case reports (Hermann and David, 1973; Okezie and DeAngelis, 1974; Arnersjo et al., 1975; Mokka et al., 1976), but few series have been reported. The management of 11 such patients is presented and the preferred treatment for this condition discussed.

Patients and methods

Between January 1967 and May 1978, 124 patients with a hepatoma were admitted to the Second Department of Surgery, Kyushu University. Six presented as spontaneous ruptures and 1 as a traumatic rupture. Between 1969 and 1974, 33 patients with hepatoma were seen at the Department of Surgery, Saiseikai Yahata Hospital, Kitakyushu. Spontaneous rupture occurred in 4 patients. Of this series of 11 patients, 9 were male and 2 female. The average age was 54 years (range 43–69 years).

The mode of presentation is summarized in *Table I*. All the patients experienced abdominal pain of mild to severe degree; the pain was sudden in onset in 8 patients but started gradually in the remaining patients. Four patients were admitted in haemorrhagic shock while 3 patients never experienced a blood pressure lower than 90 mmHg. A diagnostic paracentesis was carried out in 7 patients, and blood was aspirated in 6. Five patients had a history of liver disease: cirrhosis in 2 patients, chronic hepatitis in another 2 and schistosomiasis in 1. A correct diagnosis was made in all 7 patients who were known to have a hepatoma, but the condition was not diagnosed until laparotomy or post-mortem examination in the remaining 4 patients. The overall incidence of spontaneous rupture in 157 patients was 7 per cent.

Serum alpha-fetoprotein level was determined in 8 patients; it was elevated in 5. Hepatitis B antigen was estimated in 9 cases, and 5 showed a positive reaction.

The macroscopic appearances are summarized in *Table II*. Associated cirrhosis was present in 9 patients and fibrosis in 1 patient.

Hepatic resection was performed in 4 patients, haemostasis being achieved in all. Two of these patients died of hepatic failure 3 and 30 days after operation. The third patient lived for 2½ years, but finally died of recurrence of the tumour. One patient is alive 10 months after operation without any recurrence. Hepatic artery ligation was carried out in 3 patients and the haemorrhage was stopped in 2 of them. Only 1 of these patients lived for more than 3 months. The remaining patients who underwent packing, suture, laparotomy alone or no treatment all died within a short period following admission.

Discussion

Hepatoma is the major cause of spontaneous rupture of the liver. Recently, the rupture of hepatic adenoma by oral contraceptives has been reported in the USA (Catalano et al., 1977), but this is very rare in Japan where the contraceptive pill is prohibited. MacDonald (1957) found 4 cases of spontaneous rupture among 84 patients with hepatoma in Boston City Hospital, while El-Domeiri et al. (1971), who reported 137 cases of hepatoma from New York, did not describe a patient with spontaneous rupture. In London, only 2 cases were found in 75 hepatoma patients (Kew et al., 1971). Acute haemoperitoneum occurred in 15 per cent of Ugandan patients (Alpert et al., 1969) and in Taiwan spontaneous rupture occurred in 13 per cent of 93 patients with hepatoma (Kuo et al., 1970). A similar figure, 12·8 per cent, was reported in Hong Kong (Ong et al., 1965). The cause of rupture may be related to minor trauma; in this series 2 patients had a spontaneous rupture following medical examination and a third during a journey in an ambulance.

In the absence of a known hepatoma, diagnosis is difficult. The presence of the clinical signs of liver disease such as spider naevi, palmar erythema, gynaecomastia or jaundice should suggest the diagnosis. A paracentesis is valuable, showing a haemoperitoneum in 6 of 7 patients in this series. Emergency arteriography may locate the tumour and the bleeding vessel, although arteriography failed in 1 patient (*Case* 2) to identify the hepatoma or the site of haemorrhage.

The ideal treatment of a ruptured hepatoma is hepatic resection, and satisfactory results have been obtained by this treatment (Hermann and David, 1973; Arnersjo et al., 1975; Mokka et al., 1976).

Unfortunately, many patients with hepatoma have cirrhosis, and these patients withstand haemorrhage and hepatic resection poorly, 2 of our patients undergoing resections dying with hepatic failure during the immediate postoperative period. In patients whose liver function is impaired by cirrhosis or who have multiple tumours, resection will not prove satisfactory. For this group hepatic artery ligation is an alternative, being successful in 2 of the 3 cases in this series. In addition, ligation with or without portal vein ligation may induce tumour regression (Nagasue et al., 1976). Packing or suture of the rupture should be avoided;

all patients who had this treatment died within a short period of the operation.

The prognosis of spontaneous rupture of a hepatoma is poor. The outcome depends on the degree of coexistent cirrhosis, the position of the tumour or tumours and the general condition of the patient. Resection undoubtedly offers the better long term results, but hepatic artery ligation is worth considering as a short term management, either because of inexperience of the surgeon with hepatic resection or because the tumour is not resectable.

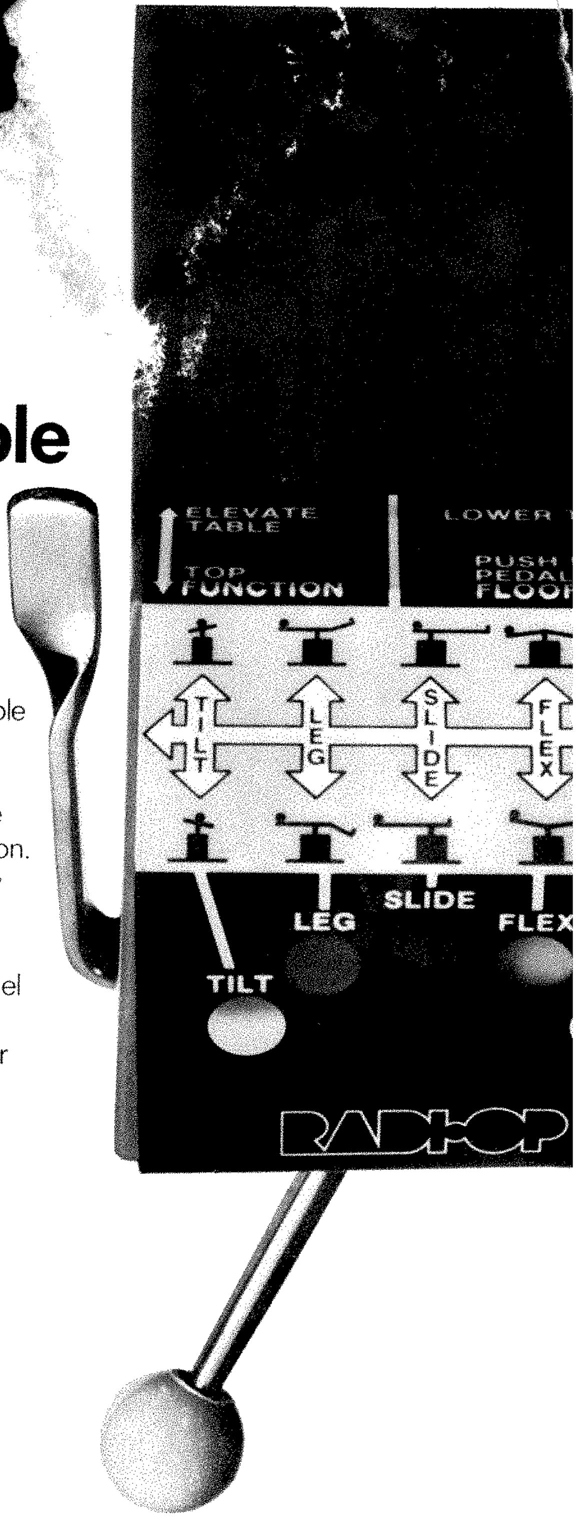
n advanced obile surgical table ith just two mple controls



Siemens Radi-op—a universal table with movable . The single movable control arm and a simple e-pedal operation gives complete mobility. The control arm smoothly positions the table to any of the six basic settings—quickly and with error-free selection.

This variety of precise positions helps make any operating procedure smoother, speedier and more efficient.

Other features include a built-in cassette channel for standard radiology procedures, a completely sealed fluid drive hydraulic system and a positive floor lock system—plus a range of accessories.

For full details write to: Siemens Limited,
Medical Group, Siemens House, Windmill Road,
Sunbury-on-Thames, Middlesex, TW16 7HS.

Statistics in *The British Journal of Surgery*

It is part of the clinical scientist's stock-in-trade to use statistical methods. In many instances, and by most readers, these can be taken on trust, but in that there is a wide variety of tests and, on occasion, disagreement amongst both amateurs and professionals on the best choice, it is always wise that authors quote the method used. It is indeed journal policy to quote methods, the reason for their choice and, in the case of clinical trials, the confidence or tolerance limits of the observed results. Delay in acceptance may occur if contributors do not include these details.

Spontaneous liver rupture i s nodosa

A. K. C. LI, J. M. RHODES AND A. R. V *

SUMMARY

An unusual case of spontaneous rupture of the liver associated with polyarteritis nodosa is reported.

SPONTANEOUS bleeding into the bowel or kidneys is a well-recognized complication of polyarteritis nodosa (Ostrum and Soder, 1960; Cabal and Holtz, 1971). Haemorrhage into the liver parenchyma has also been reported (Ayers and Fitchett, 1976), but we would like to report what we believe to be the first case of spontaneous rupture of the liver associated with polyarteritis nodosa.

Case report

A 20-year-old Norwegian girl presented with shock and severe generalized abdominal pain of sudden onset. There was no history of trauma and she was not on the contraceptive pill.

Four years previously the patient had been extensively investigated in Norway for iritis, recurrent arthralgia and pyrexia of unknown origin. It had been felt that this was likely to be a collagen disease and she was treated with prednisolone 10 mg a day which she had been taking since that time.

On examination, in addition to shock and signs of generalized peritonism, nodules were felt along both radial arteries. Following resuscitation, laparotomy was performed and 2 l of fresh blood were found in the peritoneal cavity. Arterial blood was seen spurting from a deep 8-cm laceration in the superior aspect of the right lobe of the liver. Suture of the laceration failed to control the arterial haemorrhage and a right hemihepatectomy was performed.

Histology of the resected liver showed only mild centrilobular necrosis attributable to the initial hypotension. Subsequent tests for antinuclear factor, LE cells, Latex test and hepatitis B surface antigen and antibody all proved to be negative. T cell rosetting was found to be severely diminished at 10 per cent (normal 57–73 per cent), indicating severely depressed cellular immunity. The clinical diagnosis of polyarteritis nodosa was confirmed by angiography which demonstrated numerous aneurysms in the mesenteric, renal, hepatic and splenic arteries (*Figs.* 1 and 2).

The patient's postoperative course was stormy, with a right subphrenic abscess which required drainage, oesophageal candidiasis, pneumococcal meningitis and pulmonary infarction. Furthermore, she was hypertensive (BP 230/160) with heavy proteinuria (5 g/24 h). Despite vigorous therapy she died 12 weeks after operation. A post-mortem examination was not performed.

Discussion

Spontaneous liver rupture is known to occur in association with tumours (Caldwell, 1950) and peliosis hepatis (Saeed et al., 1974), but we can find no previous report of this occurrence in association with polyarteritis nodosa, although in one case a hepatic haematoma has been reported (Ayers and Fitchett, 1976). We believe that in our patient rupture of the liver was due to massive bleeding from an aneurysmal intrahepatic artery.

This case demonstrates again the usefulness of angiography in the diagnosis and assessment of polyarteritis nodosa (Ostrum and Soder, 1960).

Acknowledgements

We wish to thank Professor K. E. F. Hobbs, Dr N. McIntyre, Dr R. Dick and Dr Barbara Ansell for their help and advice in the management of this case.

Complete liver dearterializa polvart carcinoid syndrome

GEORGE A. KHOURY, TERRY DIVINE ALEN INI OLT*

SUMMARY

A variety of surgical procedures are available in th treatment of the carcinoid syndrome, the aim being ti destruction of liver secondaries and amelioration symptoms. Dearterialization of the liver may be c sidered when liver secondaries are extensive and me treatment inadequate in controlling symptoms.

The patient reported here had severe symptoms of epigastric pain, anorexia, flushing, diarrhoea and recurrent syncope and was generally deteriorating rapidly. Complete dearterialization of the liver, however, resulted in a dramatic improvement. Now, 2 years later, the patient's hepatic scan, liver function tests and 24-h urine 5-hydroxyindolacetic acid (5-HIAA) are all within normal limits. Destruction of liver secondaries by dearterialization is a relatively simple procedure. Careful attention should be paid to large quantities of pharmacologically active compounds released from the liver during the procedure. Ascites, jaundice and liver cell failure are definite contraindications to surgery.

Carcinoid tumours occur mostly in the gut but they may occur in the biliary tract, lung, bronchi, ovary (Godwin, 1974) and, rarely, at other sites such as the urethra (Sylora et al., 1975). Pearson and Fitzgerald (1949), in reviewing a large series, found metastases in 38 per cent and emphasized that all carcinoids should be considered malignant. The carcinoid syndrome, characterized by flushing, intestinal disturbances and right-sided heart disease, develops in only about 5 per cent of patients with intestinal carcinoid tumour.

Eradication of hepatic metastases is important, as adequate relief of the systemic sequelae of the carcinoid syndrome may not be achieved with conservative therapy. Methods available include hemihepatectomy (Bersohn and Bleloch, 1967; Lannon, 1974), enucleation of tumour deposits (Stephens and Grahame-Smith, 1972) and ligation together with cytotoxic infusion (Murray Lyon et al., 1970; Aune and Schistad, 1972). Complete dearterialization of the liver in the carcinoid syndrome has been performed by McDermott and Hensle (1974) with good results and more recently by Allison et al. (1977) and by Maempel and Modlin (1978) using highly selective cannulation and embolization of the hepatic artery by the Seldinger technique. Their results were encouraging but the reported follow-up was brief.

Case report

A 56-year-old man was admitted in November 1976 with severe disabling symptoms of epigastric pain, anorexia, weight loss, flushing (related to alcohol ingestion), diarrhoea and recurrent attacks of syncope. Seven years earlier a primary ileal carcinoid tumour was resected at laparotomy and multiple secondaries in the liver noted. The patient's symptoms had failed to respond to cyproheptadine, methysergide, alpha- and beta-blockers. He required 25 Palfium tablets daily for pain. On admission he was anaemic (haemoglobin 11·5 g/dl) and cachexic, but despite an enlarged liver, there was no ascites or peripheral oedema. Chest radiographs were clear and a hepatic radioisotope scan revealed a grossly enlarged liver aun cold areas which were consistent with multipl da g. 1). Several 24-h urine collections reveale an f 5-HIAA (*Fig.* 2). Liver function tests were al nal –5). A glucose tolerance test showed a norm ose Selective angiography was performed and th demon the arterial blood supply to the liver ar vascul metastases. However, films obtained were of po quality.

Operation was performed under cover of ampicillin gentamicin. Metronidazole and oral kanamycin were g preoperatively. Through a right paramedian incision abdomen was explored. The liver was found to contain gross deposits diffusely distributed throughout both lobes other metastatic disease was apparent.

Dearterialization of the liver was then carried out by ligat the right, left and common hepatic arteries, together with right gastric and gastroduodenal arteries. All the perito attachments of the liver were divided. The gallbladder removed to prevent ischaemic necrosis. A liver biopsy firmed carcinoid tumour.

The pulse, blood pressure and electrocardiogram wer monitored during the procedure and no change was detected. Peripheral oedema associated with hypoalbuminaemia developed postoperatively, but responded to albumin infusion. Discharge of necrotic material and pus from the wound occurred on several occasions but settled spontaneously. Microscopy revealed necrotic debris and culture was negative There was a small rise in bilirubin and a moderate rise in t liver enzymes, which rapidly returned to normal. The respo of the metastatic tumour is shown by the return of urinary 5-HIAA levels to normal and a dramatic change in liver scan, which returned to normal within 6 weeks (*Figs.* 6 and 7) Symptomatically there was a dramatic response, with immediate disappearance of flushing, diarrhoea and abdominal pain. This remission is continuing to date.

Discussion

Carcinoid tumours are 'apudomas' and are thought to arise from the enterochromaffin (EC) cells of the gut (Welbourn et al., 1974; Pearse et al., 1977). Between 20 and 30 per cent of patients with carcinoids of the small bowel have a second malignant tumour which is totally unrelated (Morgan et al., 1974; Welbourn and Joffe, 1977). The majority of carcinoid tumours secrete 5-hydroxytryptamine (5-HT) together with the enzyme kallikrein, which is responsible for the formation of bradykinin in the blood. These substances are normally carried to the liver by the portal blood and inactivated (Welbourn and Joffe, 1977) but, when large deposits are present, they enter the systemic circulation and cause the carcinoid syndrome (Leading Article, 1975). It is thought that 5-HT is the agent causing diarrhoea, and bradykinin produced from the $alpha_2$-globulin fraction in blood causes the characteristic flush. Although 5-HT is a vasoconstrictor, its actions on the circulation are complex. Furthermore, bradykinin is a vasodilator and may be responsible for the hypotensive attacks (Levine, 1975). Other pharmacologically active substances have been reported in the carcinoid syndrome and they may have a role in the complexity and diversity of the symptoms. Thus, Maempel and Modlin (1978)

identified for the first time an elevated pancreatic polypeptide in the plasma of a patient with a gastric carcinoid tumour producing mainly 5-hydroxytryptophan (5-HTP), a serotonin precursor.

Diagnosis depends on the presence of 10 mg/day or more of 5-HIAA in the urine; this is estimated according to the method of Udenfriend et al. (1953). High values of 5-HIAA have been reported in non-tropical sprue and after eating fruits, notably bananas, or following ingestion of certain drugs such as phenothiazines (Leading Article, 1975). The drugs chiefly used to relieve symptoms are serotonin antagonists; α-methyldopa for flushing (Welbourn and Joffe, 1977) and methysergide and cyproheptadine for diarrhoea. Ergotamine tartrate, lysergic acid and

'Bol 148', a brominated derivative of LSD [illegible] al., 1955), were tried in the treatment of diarrhoea and flushing but without success. Cytotoxic agents such as cyclophosphamide, 5-fluorouracil and streptozotocin given systemically have brought about remission in some patients. The carcinoid tumour is slow growing and patients often survive 10–20 years (Thorson et al., 1954; Fraser, 1955). Surgery should therefore be considered in the later stages of the illness. Nevertheless, operative treatment should not be postponed until patients are moribund with hepatic cell failure, in which case mortality is markedly increased (Balasegaram, 1972). Although partial hepatectomy is the obvious choice in experienced hands, this procedure is often impossible to perform due to widespread metastases in both lobes of the liver or porta hepatis. Dearterialization of the liver is then indicated.

Breedis and Young (1964) first recognized that malignant tumours in the liver were supplied almost exclusively by arterial blood, whereas normal liver tissue received blood from both the arterial and portal systems. Dearterialization was therefore used in the treatment of many liver tumours, but the procedure carried a high mortality rate since these were terminal cases of primary or secondary carcinoma of the liver (Balasegaram, 1972).

Arterial circulation of the liver has been shown to be re-established within a few days of complete dearterialization (Bengmark and Rosengren, 1970). Nevertheless, necrosis of hepatic tumours occurs following very short periods of arterial ischaemia (Almersjo et al., 1966). Complete dearterialization of the liver is difficult to achieve unless all attachments between the liver and the surroundings are carefully divided except the common bile duct, the portal vein, hepatic veins and inferior vena cava (Bengmark and Rosengren, 1970). Collateral vessels most commonly arise from the inferior phrenic artery or the intercostal arteries. The lesser omentum should be detached from the liver lest an aberrant left hepatic artery be missed (Michels, 1953). Preoperative angiography to show the liver circulation and collaterals is mandatory. Splenoportography is indicated before surgery to exclude thrombosis or portal vein infiltration by tumour (Balasegaram, 1972). A full preoperative work-up should be carried out, including a glucose tolerance test. Feldman et al. (1975) clearly demonstrated that 80 per cent of patients with the carcinoid syndrome had impaired insulin secretion and intolerance to glucose.

During the operative procedure central venous pressure and electrocardiogram recordings should be continuously monitored. Two intravenous infusion routes are preferably kept open to facilitate very rapid fluid or blood replacement should this be necessary. Hypotensive episodes and, occasionally, collapse are reported to occur following anaesthesia and during dearterialization (Levine, 1975; Maempel and Modlin, 1978). Levine suggests the use of either phenylephrine or angiotensin in the treatment of hypotension. Maempel and Modlin administered the antikinin agent aprotinin and steroids during the procedure of embolization and for the following 24 h by continuous intravenous infusion. In addition to these precautions, Allison et al. (1977) gave parachlorophenylalanine 500 mg every 6 h for 48 h before embolization to reduce release of 5-HT during tumour necrosis. Hypotension during hepatic artery [illegible] with a high incidence of hepatic [illegible] (Mays, 1967) and should be [illegible] antibiotic therapy is important in [illegible] emia.

Postopera[illegible] McDermott and Hensle (1974) reported a purulent discharge from the wound which revealed 'ghost [illegible] consistent with carcinoid origin. Similarly, in our patient, a discharge occurred which drained white creamy material for a period of 5 weeks. Microscopy revealed only debris and pus cells. No organisms were grown on culture media.

In patients with the carcinoid syndrome, the availability of the essential amino acid, L-tryptophan is reduced and consequently synthesis of albumin and nicotinic acid may be restricted (Swain et al., 1976). It is noteworthy that our patient developed severe peripheral oedema in the postoperative period. This responded well to albumin infusion and spironolactone therapy.

Finally, liver dearterialization seems to have a place in the treatment of the carcinoid syndrome. Whether this is achieved by embolization as shown recently by Maempel and Modlin (1978), or by surgical means, is a matter of choice, and depends on availability of radiographic expertise. The correct timing of this treatment is important and, although the reported numbers of patients undergoing complete dearterialization are small, we feel encouraged having learned that this patient is now able to run 3 miles each morning, has returned to work and is enjoying a full and active life, 2 years following dearterialization of the liver.

Acknowledgements

We are grateful to Dr R. F. Jewkes, Department of Nuclear Medicine, Charing Cross Hospital, for his invaluable help with the radioisotope scans and to Miss S. H. Wilkinson for typing the manuscript.

ave been no episodes of c [illegible] fit and active and has ga [illegible] height since the operation.

[illegible] specimen consisted of the enlarged gall [illegible] a [illegible] herent 3-cm mass encasing the common he [illegible], [illegible] and common bile ducts (*Fig.* 2). The cystic duct was completely occluded and a probe was passed through the common hepatic and common bile ducts with difficulty. The tumour was encapsulated, a mottled yellow-brown in colour and had a soft centre. Sections of the encased bile duct showed patchy loss of epithelial lining, loss of muscle coat and replacement by collagenous fibrous tissue. There were foci of acute inflammatory cells around the bile duct remnants. Sections [illegible] surrounding tumour bulk showed similar sheets of collagenous fibrous tissue with a mixed inflammatory cell infiltrate (*Fig.* 3). Within the central mass of tumour there [illegible] a large area of lymphoid tissue with reactive follicular hyperplasia.

ssion

istological features of this lesion are unusual and not described in standard texts. They are, however, similar to a single case previously reported by ith et al. (1964), who described a histologically benign mass surrounding the distal common bile duct in a 6-year-old boy. Because of its tumour-like appearance at operation, excision was by pancreatico-duodenectomy. The lesion was spherical, 3 cm in diameter, with a firm, yellow-tan cut surface. The tumour mass was entirely benign, being composed of bundles of fibroblasts and collagen fibres with large numbers of chronic inflammatory cells scattered throughout. The encased bile duct showed loss of epithelium with dense surrounding fibrous tissue. On the basis of these microscopic findings, these authors ed t [illegible] ion ‘an inflammatory pseudotumour’ of [illegible] common bile duct.

[illegible] these microscopic and histological features accord [illegible] those of the tumour presented in this paper, [illegible] we believe is a second case of this histologically [illegible] lesion. The location of the tumour reported [illegible] in the proximal part of the extrahepatic biliary tr [illegible] probably accounts for the well-defined area of ly[illegible] id tissue with follicular hyperplasia which mi[illegible] represent the cystic lymph gland. The aetiology of [illegible] tumour must be speculative, but it seems to rep[illegible] an excessive inflammatory reaction to some loc[illegible] irritant that might be chemical or infective in nature. One further possibility might be that the lesion represents a form of sclerosing cholangitis, though its localized nature would be unusual as would the loss of bile duct epithelium and the encapsulated nature of the tumour. In addition, the child reported here has remained well in the 21 months of follow-up.

The prognosis would seem to be excellent and relate not to the tumour, which is histologically benign, but to the technical problems involved in surgical resection and reconstitution of biliary drainage.

Benign inflammatory tum mon bile duc

J. D. STAMATAKIS, E. R. HOWARD A LL AMS

SUMMARY

A rare cause of obstructive jaundice in childhood presented. Ultrasound and subsequent percutaneou cholangiography demonstrated the te of obstructio Histological examination of the re ted tumo showed features consistent with a diag is of beni inflammatory tumour of the common bile duct.

A CASE of obstructive jaundice in a child resulting from encasement of the extrahepatic biliary tree by an inflammatory mass is described. The obstructing lesion, which at surgery closely simulated a tumour, has been reported only once previously, being described on that occasion as an inflammatory 'pseudotumour' of the bile duct (Haith et al., 1964).

Case report

A previously fit 13-year-old girl was referred because of jaundice and abdominal pain of 12 weeks' duration. The stools were pale and the urine dark. On examination she was deeply jaundiced, though without the stigmas of chronic liver disease. The liver was smooth, tender and enlarged to mid-way between the costal margin and the umbilicus. The gallbladder was palpable. There were no other abnormal physical signs.

Full blood count and film, autoantibodies, HBsAg, serum proteins and blood chemistry were normal. Prothrombin time was not prolonged (vitamin K given before referral), ESR 81 mm/h, bilirubin 230 μmol/l, alkaline phosphatase 1400 i.u./l and aspartic acid transaminase 166 i.u./l. Abdominal ultrasound revealed a solid mass around the common hepatic and common bile ducts. Hepatic arteriography showed a faint blush below the liver, suggesting a relatively avascular tumour. Percutaneous cholangiography with a fine-needle technique (Okuda et al., 1974) demonstrated that the biliary system was dilated to a point in the common hepatic duct at which there was complete hold-up of contrast medium with intraluminal shouldering (*Fig.* 1). The gallbladder was not visualized.

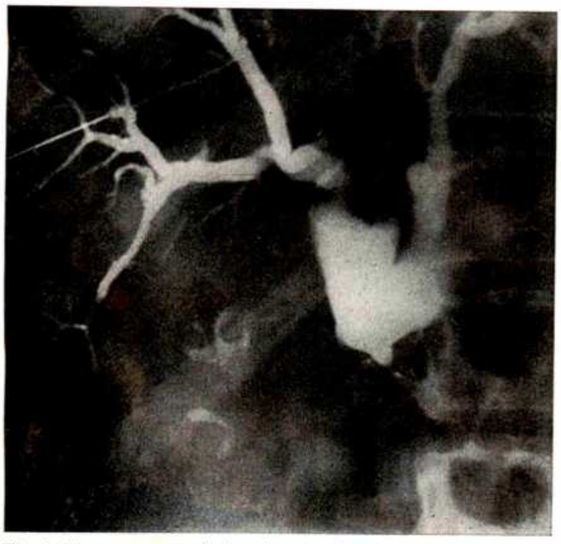

Fig. 1. Percutaneous cholangiogram showing a dilated intrahepatic biliary tree and common hepatic duct. There is complete hold-up of contrast medium in the distal common hepatic duct.

f oper on a distended ga ladder was first aspirated clear mucus. There was a 3-cm spherical tumour closely applie to the porta hepatis and involving the upper common bile duc cystic duct and common hepatic duct. The tumour w excised with the common hepatic and common bile ducts a he confluence of the right and left hepatic ducts was drai by a 25-cm Roux-en-Y loop of jejunum. In addition, a l accessory right hepatic duct required separate implanta into the Roux loop. The child made an uneventful reco from this procedure and was maintained on intermittent a biotic therapy for 1 year. Since this was stopped 9 months

Hepatic artery aneurysm [illegible]ary surgery

A. HUBENS AND A. DE SCHE[illegible]ER*

SUMMARY

This paper describes a patient operated upon f[illegible]l-bladder and bile duct stones, who presented [illegible] an extrahepatic aneurysm of the main hepatic [illegible]ial trunk and with a central intrahepatic haematoma assumed to be caused by the rupture of [illegible] intrahepatic aneurysm or by secondary intrahepatic necrosis. Exploration of the bile ducts resulted in haemobilia. The presence of extrahepatic arterial collaterals precluded individualization of the left and right hepatic arteries and subsequent distal arterial ligation or partial hepatectomy. Ligation of the common hepatic artery, although initially successful, was insufficient to avoid a recurrent and fatal haemobilia.

ANEURYSMS of visceral branches of the abdominal aorta are rare. The greatest number of these aneurysms involve the splenic (46·9 per cent) and the hepatic (16·2 per cent) arteries. Lataste et al., reviewing the world literature on aneurysms of the hepatic artery in 1971, stated that about 250 cases had been reported at that time. Aneurysm of the hepatic artery is an uncommon entity and the diagnosis is seldom made preoperatively, especially when the patient presents with bile duct stones which could explain his complaints. Angiography may identify the lesion but the majority of hepatic aneurysms have been discovered at post-mortem examination. About 60 cases have been successfully managed by surgery (Harlaftis and Akin, 1977). Hepatic aneurysms constitute a pitfall in diagnosis and treatment, and they may give rise to serious complications in biliary surgery, as described in the following case report.

Case report

A 69-year-old man was admitted to the surgical wards of Stuivenberg Hospital, Antwerp, on 20 June 1977. He complained of attacks of colicky pain in the right hypochondrium during the previous 4 weeks, radiating to the back and occurring mainly after fatty meals. He had never experienced such pains before. In his past history there were no symptoms of previous abdominal illness. He had never been jaundiced or sustained any abdominal trauma. He had had an operation for an inguinal hernia several years previously. He did not drink or smoke and had always lived in Western Europe.

Examination revealed a pale, thin man, who was afebrile and anicteric. The abdomen was flat and not tender. A recurrent right inguinal hernia was present. No other abnormal masses were felt. The liver and spleen were not palpably enlarged and further physical examination was normal.

The red blood cell count on admission was $4{\cdot}2\times10^{12}$/l, the white cell count $7{\cdot}2\times10^{9}$/l with 58 per cent polymorphonuclear cells. An intravenous cholangiogram demonstrated several stones in the gallbladder and, in addition, one in the distal bile duct. At the same time a calcified, oval structure about 1 cm in length was visible, medial to the porta hepatis (*Fig.* 1).

On 22 June 1978 laparotomy for removal of the gallstones was performed. The gallbladder was not inflamed and contained several stones. The common hepatic duct was surrounded by a net of pulsating vessels. A firm, nodular structure could be palpated in the medial part of the lesser omentum. A tentative diagnosis of aneurysm of the hepatic artery with collateral circulation to the porta hepatis was made.

A peroperative cholangiogram was performed via the cystic duct, which confirmed the presence of a stone in the distal bile duct. The common bile duct was freed from the surrounding arterial branches and choledochotomy was performed. The bile duct contained some 'mud' and a stone was extracted by means of Desjardins forceps. On exploring the left and the right hepatic ducts with a Fogarty biliary balloon catheter, haemorrhage occurred into the lumen of the bile ducts, but this ceased spontaneously after a few minutes.

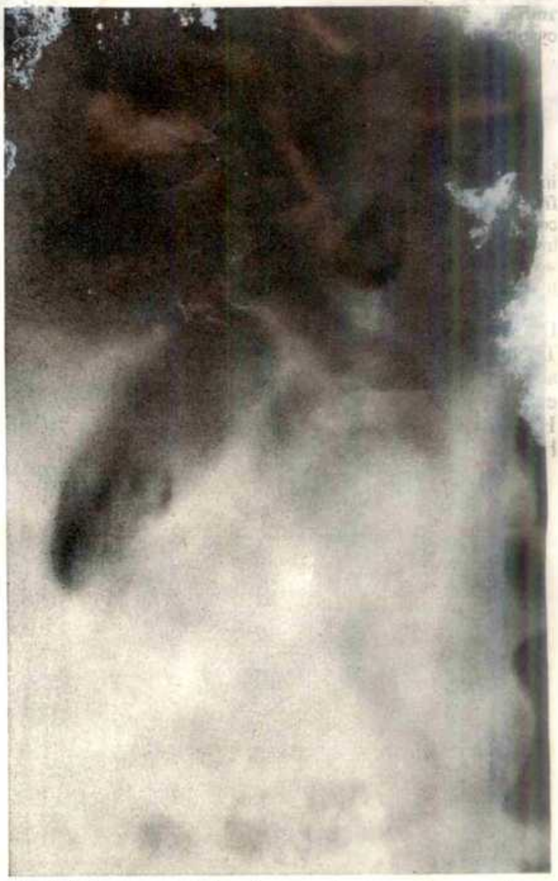

Fig. 1. Intravenous cholangiogram showing a stone in the distal bile duct and a calcified oval structure medial to the porta hepatis.

Retrograde cholecystectomy was performed and a T tube inserted in the common bile duct to allow biliary decompression. The subhepatic space was drained by a multitubular drain brought out through a small incision opposite the tip of the eleventh costal cartilage.

During the first postoperative week the patient's progress was uneventful and haemorrhage did not recur. On 1 July 1978 a cholangiogram was performed via the T tube drain. This demonstrated not only the absence of intraductal stones but also a progressive extravasation of contrast medium in a centrally located intrahepatic cavity. Immediately after cholangiography brisk bleeding commenced through the long arm of the T tube and also via the abdominal drain.

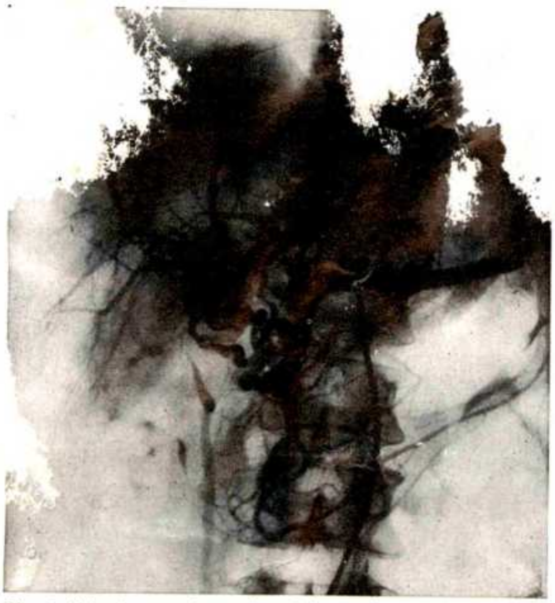

Fig. 2. Selective arteriography of the coeliac trunk showing that the extrahepatic aneurysm stops the main blood flow to the liver which is irrigated by vessels originating from the coeliac trunk.

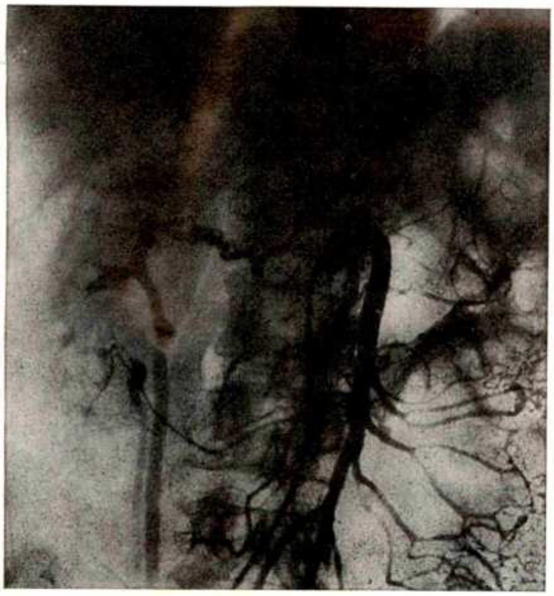

Fig. 3. Selective arteriography of the superior mesenteric artery showing the calcified aneurysm and collateral vessels to the liver originating from the superior mesenteric artery. A central intrahepatic haematoma displaces the blood vessels.

Three units of blood were transfused and the condition of the patient improved. Selective arteriography of the coeliac trunk and the superior mesenteric arteries was carried out. These studies demonstrated the presence of a thrombosed aneurysm of the hepatic artery. The liver was supplied by a net of collateral vessels, originating mainly from the coeliac trunk but also from the superior mesenteric artery. Distal to the thrombosed artery a large cavity was demonstrated, located in the central part of the liver at the bifurcation of the

ures (*Figs.* 2, 3). On 9 July 1977 the patient presented recurrent haemorrhage through the drains. Repeated sions were unable to stabilize his condition. Emergency my was undertaken. On opening the abdomen, the ic space was observed to be filled with clot. The of arterial collaterals precluded elective clamping of tructures, and the central liver cavity appeared to be nd too centrally located to be opened in order to leeding vessels without immediately endangering ife. The only apparent way to control the situa- be to lig e the main arterial supply to the liver. patic artery was ligated at its origin from the a oximal to the collateral vessels. The active lin but immediately after this procedure, the nt in iced. Hepatic function was lowest on 15 bu radually thereafter as did the patient's gen .

On 30 patient developed a new, acute haemorrhagic episode. He pr nted with melaena and bled massively via the drains. Emergency endoscopy confirmed the absence of gastrointestinal ulceration but demonstrated active bleeding through the ampulla of Vater. Despite massive transfusion (20 units) the patient died in hypovolaemic shock on 1 August 1977.

A post-mortem examination confirmed the peroperative findings. The distal portion of the hepatic artery was occluded by a calcified and thrombosed aneurysm. A large net of collaterals had developed towards the liver and the hepatic artery was ligated at its origin, proximal to these collaterals. A vast, necrotic, haemorrhagic cavity occupied the central portion of the liver and communicated with the right hepatic duct. The whole intestinal tract was filled with blood from the ampulla of Vater downwards. No oesophageal varices or gastroduodenal ulceration could be demonstrated.

Discussion

The world literature on aneurysm of the hepatic artery has been extensively reviewed by Guida and Moore (1966), Deterling (1971) and Erskine (1973). Two main types of aneurysm occur—saccular and dissecting. Saccular aneurysms occur most frequently. They may be congenital or secondary to acquired disease such as atherosclerosis, infection or trauma. Dissecting aneurysms may be primary and restricted to the involved artery, but sometimes they are secondary, presenting as a complication of the relatively common dissecting aneurysm of the aorta (Hill and Edwards, 1974). Most aneurysms are single but some patients do present with multiple aneurysms of the visceral abdominal arteries.

Two-thirds of the reported cases have been extrahepatic. They may rupture into the free peritoneal cavity or into an adjoining structure—the bile ducts, gall bladder, duodenum or portal vein. Perforation into the bile ducts leads to haemobilia, characterized by gastrointestinal bleeding, biliary colic and jaundice. Perforation into the peritoneal cavity followed by shock is relatively frequent.

Intrahepatic aneurysms are less frequent and less well known. The right hepatic artery is more frequently involved than the left. Rupture of an intrahepatic aneurysm may cause the formation of an intrahepatic haematoma. Erskine (1973) reported a patient presenting with an intrahepatic haematoma that had been caused by a ruptured aneurysm that resolved spontaneously. Generally speaking, however, these haematomas lead to a rupture of the liver capsule with secondary intraperitoneal bleeding.

Symptoms before rupture has occurred are nonspecific and may even be absent. Selective angiography of the coeliac axis or the superior mesenteric artery is at present the most reliable diagnostic tool. This investigation is mandatory in any case in whic[illegible] clinical history of haemobilia or the presence [illegible] calcified shadow in the liver area on X-ray ex[illegible]tion suggests the possibility of a hepatic [illegible] aneurysm. Moreover, selective angiograp[illegible] localize the aneurysm precisely and may be of importance in planning its management.

The treatment of an aneurysm of the hep[illegible] especially the intrahepatic variety, is still [illegible] discussion. Ligation of the hepatic arter[illegible] with excision of the aneurysm are [illegible] n[illegible] commonly employed procedures (Har[illegible] A[illegible] 1977; Taylor and Dawson, 1978). In [illegible] case[illegible] graft reconstruction has been performe[illegible] [illegible]xcision of the aneurysm (Danielson et al., 196[illegible] R[illegible]ten and Sikkenk, 1971; Goldman and Stone, 1974). Some patients have been successfully treated by percutaneous embolization of a branch of the hepatic artery (Goldblatt et al., 1977).

Survival following hepatic artery ligation depends on increased extraction of oxygen from the portal blood as well as on the remaining arterial supply to the liver (Madding and Kennedy, 1972). A rapid development of collateral vessels has been demonstrated by angiographic studies in man (Bengmark and Rosengren, 1970). According to Mays (1967), the increased extraction of oxygen from portal venous blood appears to be the major compensatory mechanism after hepatic arterial flow is cut off. Factors which reduce portal venous flow or increase hepatic oxygen requirements should be avoided.

When the hepatic aneurysm is proximal to the gastroduodenal artery, an excision may be safely performed. The gastroduodenal artery will then supply the liver with arterial blood from the superior mesenteric artery via the pancreaticoduodenal arcades. When the extrahepatic aneurysm is distal to or on the gastroduodenal artery, reconstruction of the arterial blood flow to the liver after excision of the aneurysm is mandatory. This may be performed by a direct anastomosis, by a vascular graft, by mobilization of the splenic artery or by endo-aneurysmorraphy. A trial period of arterial occlusion and observation of the liver for colour changes may give useful information as to whether a reconstruction of the interrupted arterial flow is necessary (Erskine, 1973).

When the aneurysm is intrahepatic, and moreover when it has caused an intrahepatic haematoma or haemobilia, management is a delicate problem. Knowledge of the exact location of the lesion is essential in order to proceed either to ligation of the right or left branch of the hepatic artery or to excision of the involved liver segment or lobe.

Reconsidering the case history of our patient, it is highly probable that he presented with a simultaneous ruptured intrahepatic aneurysm and an obliterating extrahepatic aneurysm on the distal hepatic artery, as well as bile duct stones.

A space-occupying intrahepatic lesion displacing bile ducts and blood vessels was shown on peroperative cholangiography as well as on post-operative selective angiography. Peroperative exploration and post-mortem examination proved this lesion to be a cavity filled with blood, assumed to be a ruptured intrahepatic aneurysm. Nevertheless, one must admit that the impairment of the arterial flow to the liver might also have been responsible for the development of secondary intrahepatic necrosis, th[illegible]ation of this central [illegible] [illegible]. [illegible]ative [illegible]ration of the [illegible] [illegible]ulted in [illegible] communication betw[illegible] [illegible] duct and the intrahepatic [illegible] [illegible]ing in haemobilia. The treatment of [illegible] [illegible]es either the ligation of the bleeding [illegible] excision of the involved liver segment or lobe (Taylor and Dawson, 1978).

An attempt to locate the central intrahepatic haematoma was not successful in practice. Owing to the obliterating extrahepatic aneurysm on the distal hepatic artery and the collateral circulation to the porta hepatis, neither the right nor the left hepatic artery could be individualized on angiographic examination, nor could they be electively clamped during surgical exploration.

Wilkinson et al. (1968) reported 3 cases of post-traumatic haemobilia which responded favourably to ligation of the common hepatic artery, but various authors have pointed out that not all patients with intrahepatic bleeding due to ruptured aneurysm will be controlled by such means (Bruwer and Hollenbeck, 1957; Guynn and Reynolds, 1961; Erskine, 1973).

A study of arterial prostheses by scanning electron microscopy

P. F. CONWAY, S. C. SIMMENS AND D. CHARLESWORTH*

SUMMARY

Scanning electron micrographs were taken of ten different vascular prostheses. The micrographs showed that some prostheses were damaged and some had traces of chemicals on their surface. The application of standard vascular clamps damaged most grafts and some showed remarkable changes on resterilization.

MOST arterial prostheses are made from synthetic fibres, usually Dacron or Teflon, and a new generation of prostheses for large arteries has recently become available, specifically made to have a higher porosity than their predecessors. There is now a wide choice of prostheses; the differences between them are small and selection tends to be arbitrary. As part of a larger project to compare the mechanical properties of the various prostheses we took photomicrographs of their surfaces and investigated the effects on them of resterilization.

Materials and methods

Specimens of fabric were chosen from amongst batches of prostheses supplied to the hospital by the manufacturers. They were all sterile and ready for implantation.

The samples were coated with a layer of gold atoms by the process of sputter coating (Allan and Simmens, 1976). Particles of atomic dimensions are ejected from a target cathode as a result of momentum transfer between incident ions (gas ions accelerated by a high voltage) and the target. These particles traverse a vacuum chamber and are deposited on the specimen as a thin film.

Several samples from each prosthesis, each approximately 0·25 cm² in surface area, were mounted without tension, and with either the inner surface or the outer surface uppermost.

We used a Jeol JFMI scanning electron microscope in conjunction with a Mamiya camera and 127 film. Several photographs were taken of each sample of fabric at magnifications of ×33, ×100, ×1000, ×3000 and ×10 000. The photographic prints were in black and white and measured 18×14·5 cm.

To examine the effects of sterilization, lengths of each prosthesis were cut into three pieces; one piece was sterilized once, another twice and the third piece three times. To obtain a picture of each prosthesis in cross-section the outer surface of a sample of prosthesis was marked before embedding it in Silastic. Samples were embedded under various degrees of tension. They were then cut lengthways (i.e. perpendicular to the crimp) and mounted with the cut surface exposed. The size of the interstices between bundles of yarn (pore size) and the roughness of the internal surface could be estimated from photographs of these preparations.

Results

We examined seven types of prosthesis made from Dacron, two from Teflon and one made of expanded polytetrafluoroethylene (PTFE). 1, Cooley double velour knitted Dacron; 2, Cooley knitted Dacron; 3, DeBakey knitted Dacron; 4, DeBakey woven Dacron; 5, DeBakey Vasculour 'D' internal velour knitted Dacron; 6, DeBakey 'Ultra Lightweight' knitted Dacron; 7, Sauvage double velour knitted Dacron; 8, Edwards knitted Teflon; 9, Edwards woven Teflon; 10, Gore-Tex (expanded PTFE).

Gore-Tex prostheses are dissimilar to all the others in that they are made from expanded polytetrafluoroethylene rather than being woven or knitted. A layer of expanded PTFE was seen to be sandwiched between two outer skins, also made from PTFE but of a different composition. When this prosthesis was clamped [illegible] compression marks were visible to the naked eye (*Fig.* 1). Microscopically, the fibres were found to be compressed with no intervening spaces. All the other prostheses were made of fibres with a circular cross-section except for the Cooley double velour. This prosthesis was made up of two shapes of fibres, one having a circular cross-section and one having a trilobal cross-section. At high magnification (×10 000) the fibres of this prosthesis were found to have traces of a finish on the surface (*Fig.* 2). Successive extractions with boiling solvents, water, petroleum ether, acetone, methanol and toluene removed very small amounts of material. These were identified by infrared spectroscopy as polyester oligomer and what was almost certainly a spinning or knitting lubricant containing tallow. A finish was also detected on the surface of the Edwards knitted Teflon graft.

The fibres of some prostheses were damaged, principally on the ridges of both the inside and the outside surfaces, where they appeared to be crushed and split. This type of damage was most marked in samples of woven Teflon and was present in all the Teflon prostheses we examined (*Fig.* 3). In addition, tiny strands of Teflon were found to stretch between the fibres and across the surface of the individual fibres. These microfibres were only seen at a high magnification (×3000).

There was little or no change in most prostheses after resterilization, but the Cooley knitted Dacron graft showed remarkable changes. When the prosthesis was first examined the surfaces of individual fibres were smooth except for a few crystals of cyclic oligomer. After a further resterilization a few more crystals appeared on the surface, and after three resterilizations the fibres appeared to be coated with a thick layer of crystals (*Figs.* 4 and 5). Other Dacron grafts were not affected in this way although the fibres were apparently similar before resterilization.

Clamping the knitted and woven prostheses did not damage the individual fibres, but it did slightly crush the knit or weave, changing the structure of the interstices.

Discussion

The method of manufacture is fairly standard—synthetic fibres are extruded and then spun together to form a yarn. The shape of the fibres is determined by the shape of the nozzle through which they are

extruded. During the spinning process the fibres are passed through a tank of 'spin finish' which contains antistatic (this helps to repel particles of dust that adhere to the fibres and allows one thread to slip over another in the knitting and weaving processes). The yarn is knitted in one of two ways—warp or weft. In weft knitting a tube is knitted in a spiral using only one or two yarns; warp knitting is a more complicated process, a series of tubes being knitted at the same time. Inevitably oil from the machinery is absorbed into the yarn during these processes. The tubes are then bleached, scoured and washed in various wetting agents and solvents to remove the spin finish, oil and other impurities. The tubes are crimped by placing them over a mandrel, a strong thread is wound round in a spiral and then heat-set in that position. Further finishes may be applied to make the graft easier to handle or to make it waterproof. Some grafts, the knitted Teflon and the Cooley double velour, still had traces of a finish on them and the woven Teflon was damaged extensively where the crimps had been set during the manufacturing process. Woven Teflon prostheses are virtually impervious and are seldom associated with aneurysm formation, so

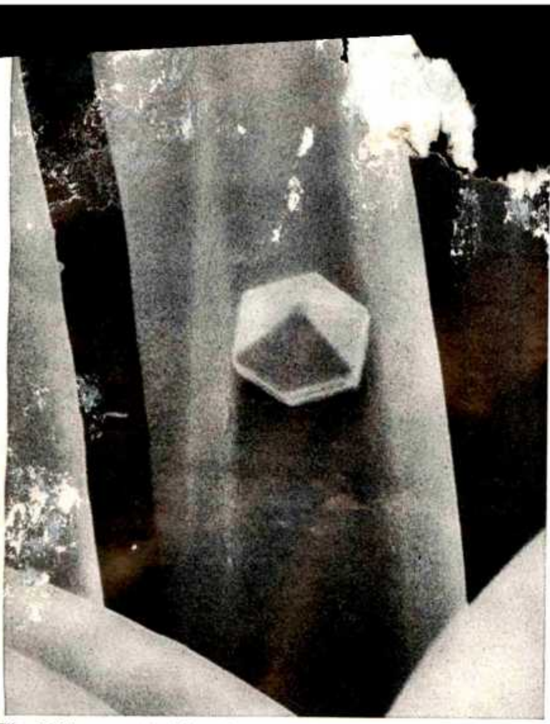

Fig. 5. Sauvage double velour prosthesis (× 4700), showing a single cyclic oligomer crystal on the surface of a fibre.

the damaged fibres do not seem to alter their strength materially. We were unable to identify precisely what 'finish' remained on the yarn of the Cooley velour graft but it appears to be a water-repellent. This suggests that either the scouring processes are not thorough enough or that a finish is applied after the washing process to modify the properties of the fabric. If the latter is the case then by the time the prosthesis reaches the consumer considerable amounts of the finish have flaked off. The Teflon prostheses, both knitted and woven, were interesting in that tiny strands of Teflon were seen to be stretched between individual fibres. These microscopic strands were only seen at high magnification and presumably formed after the fabric was woven.

ron showed remarkable ization. A coating of crystals of was seen over the fibres of the yarn, a ch became increasingly thick with each sequent resterilization. It seems likely that the polymers which make up the fibres break up into smaller chains, some containing only a few monomer units. These monomers may then crystallize at the surface. A coating of such crystals may have deleterious effects, it may interfere with the adherence of the pseudointima or the crystals may be washed away. Our preliminary investigations show that cyclic oligomer crystals can cause haemolysis but there is no apparent effect on the coagulation of blood.

Of all the prostheses, only Gore-Tex was permanently damaged by clamping, but the manufacturers do warn that the material should not be handled by instruments or clamped tightly. When the material was clamped the fibres were fused together, obliterating all the intervening spaces. This would prevent infiltration of fibroblasts and may affect the formation of a satisfactory intima. The other prostheses were not damaged to the same extent, but again the interstices between fibres were altered and the consequences may be the same.

The changes produced by clamping can be avoided with care, but those produced by resterilization cannot. Most prostheses are supplied ready for use but it is occasionally necessary for the sake of economy to resterilize a prosthesis or part of it. We were scrupulously careful to follow the manufacturers' recommendations when resterilizing the prostheses. Crystals of cyclic oligomer appeared on all Dacron fibres but were more apparent in the Cooley knitted Dacron graft.

We started this work as a preliminary to measuring the porosity of various prostheses and we were surprised to find that the quality control applied to some of the grafts we examined was less stringent than we might have hoped. It seems that the process of manufacture can result in permanent damage to arterial prostheses and introduce chemicals into the body, the effects of which are as yet unknown.

Assessment of carot[illegible] using pulse wave transit time

M. HORROCKS, V. C. ROBERTS AND L. T. COTTON*

SUMMARY

A prospective study has been undertaken on 24 patients to establish the relationship between the degree of internal carotid artery stenosis, as estimated by arteriography, and the pulse wave transit time in the carotid artery. The technique involves the simultaneous [illegible] of two continuous wave Doppler velocimeters, one on the carotid and one on the supraorbital artery, to measure the flow waves and hence deduce the pulse wave transit times. The measured transit times varied from 17 to 124 ms with a beat-to-beat variation of 11 per cent.

The absolute transit time in any segment correlated moderately well with the estimated degree of stenosis ($r = 0{\cdot}68$, $P < 0{\cdot}001$). However, normalization of the transit times, to correct for the effects of blood pressure and age, produced an improved correlation between the variables ($r = 0{\cdot}8$, $P < 0{\cdot}001$). Normalization was achieved by dividing the common carotid to supraorbital transit time by the shortest transit time found between the common carotid and either the superficial temporal or brachial arteries.

Significant differences in the normalized transit times were found between arteries that were diametrically stenosed by more than 50 per cent, by between 21 and 50 per cent and by 20 per cent or below. It is concluded that pulse wave transit time measurement can provide a simple and reproducible non-invasive technique for the diagnosis of varying degrees of carotid artery stenosis.

THE annual reports of the Registrar-General for England and Wales indicate that the overall mortality from cerebrovascular disease is increasing and currently accounts for 13 per cent of all deaths. The death rate has risen from 1226 per million population per year in 1965 to 1525 per million population per year in 1975, the incidence being 50 per cent greater in women than in men.

Many patients with cerebrovascular disease present with transient ischaemic attacks (TIAs) and it has been shown that approximately 30 per cent of these patients, if left untreated, are likely to develop a stroke within 5 years (Fields et al., 1970). Patients who present with an asymptomatic carotid bruit pose a further problem. Javid et al. (1970) have shown that in 34 per cent of patients with an asymptomatic carotid bruit there is progression of the degree of stenosis by more than 25 per cent per year. It has been suggested that if patients with asymptomatic bruit are left untreated 46 per cent will develop transient ischaemia or frank stroke within 10years (Thompson et al., 1976). Recent studies (Kartchner and McRae, 1977) have indicated that, of those patients with TIAs, those who are most likely to have a stroke are the ones with a rapidly increasing carotid stenosis.

Surgically accessible extracranial carotid artery disease has been found in approximately 35 per cent of all cases of ischaemic cerebrovascular disease (Fields et al., 1968). The recent improvement in the understanding of the physiology of the cerebral circulation, combined with increased surgical and anaesthetic expertise, has resulted in minimal operative mortality and morbidity in carotid endarterectomy. Thus, many patients with transient ischaemic attacks or increasing carotid stenosis are now treated surgically to prevent strokes.

Since the first recorded case of successful carotid artery reconstruction for recurrent cerebrovascular symptoms (Eastcott et al., 1954), there has been increasing interest in carotid artery surgery. Until recently, the only way of assessing carotid artery disease has been carotid arteriography, by direct puncture or via the aortic arch. However, [illegible] arteriography is expensive, requires very expert radiology and is potentially hazardous. Reported mortality and morbidity is 0·7 and 0·5 per cent respectively (Hass et al., 1968).

Any non-invasive technique which could approach the accuracy of arteriography would offer great advantages, allowing the monitoring of patients with asymptomatic bruits and selecting patients with TIAs into those with increasing carotid stenosis, i.e. those who are at greatest risk from stroke and would therefore benefit most from prophylactic surgery.

Many non-invasive techniques for diagnosing carotid artery stenosis have been reported in the literature. The first technique, attributed to Brochenbrough (1964), is based on detecting the direction of flow in the supraorbital artery using an ultrasonic velocimeter. This simple test has been found, however, to be only 60 per cent accurate in diagnosing lesions of greater than 75 per cent stenosis. Other developments have included pneumo-oculoplethysmography (Gee et al., 1974, 1976), phonoangiography (Kartchner et al., 1973; Duncan et al., 1975), thermography (Wood et al., 1965), rapid sequence scintiphotography (Maynard et al., 1969), ocular plethysmodynamometry (Sand et al., 1975) and fluid-filled oculoplethysmography (Kartchner et al., 1973). Of these techniques, fluid-filled oculoplethysmography has been reported as the most accurate (Gross et al., 1977), being approximately 80 per cent accurate at diagnosing haemodynamically significant stenoses.

The major drawbacks of many of these methods are that they are costly in terms of both equipment and staff, and in some cases are distinctly unpleasant for the patients. Accordingly a great deal of attention has been focused on the application of Doppler ultrasound (Brinker et al., 1968; Grossman and Wood, 1968; Maroon et al., 1969; Wise et al., 1971; Machleder, 1973; Mol and Rijcken, 1974; Baskett et al., 1977). All of these techniques offer the potential for investigating repeatedly, safely and atraumatically the patency of a specific vessel segment. In practice, however, none of the available ultrasonic techniques has been found to be capable of reliably detecting diametral stenoses of less than 60 per cent. The application of ultrasonic velocimetry to the diagnosis

of disease in the leg has indicated that the measurement of pulse transit times can be a sensitive indicator of arterial occlusion especially when normalized to compensate for changes in blood pressure and age (Cotton et al., 1976). This present work is the result of an attempt to apply this finding to the diagnosis of carotid artery disease.

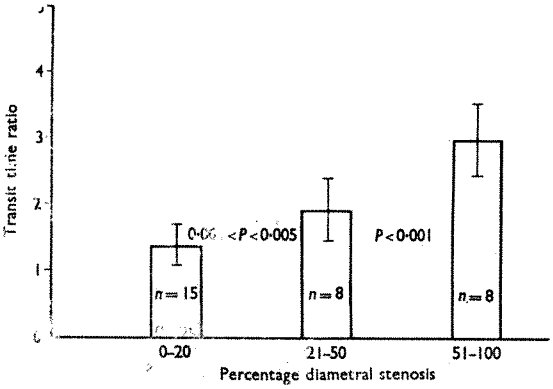

Fig. 4. Transit time ratio in the three groups of patients.

Patients and methods

Twenty-four patients (15 men and 9 women) who were to undergo carotid arteriography, mainly for symptoms of transient cerebral ischaemia, were assessed by the technique. The ages of the patients ranged from 34 to 77 years with a mean of 59 years. All patients had both carotid arteries studied, and the results were recorded and processed before arteriography was undertaken.

Arteriography

Most of the patients had direct puncture carotid arteriograms, with biplanar views of the carotid bifurcation and the whole of the extra- and intracranial arteries. The carotid arteriograms were assessed blind by three independent observers all experienced in reporting carotid arteriograms. Each observer individually assessed the percentage of narrowing of the internal carotid artery by taking the transverse diameter of the narrowest lesion and comparing this to the nearest adjacent normal calibre carotid artery. These figures were then averaged to produce a mean figure for further correlation.

Where there was significant disagreement in the interpretation of the X-rays, particularly when the quality of the X-ray was so poor that it was felt unreasonable to compromise, then the patients concerned were excluded.

Methods

The pulse wave velocity in the internal carotid artery system was assessed by measuring the time taken for the pulse wave to travel to the supraorbital artery from the common carotid artery. The supraorbital artery is a major branch of the ophthalmic artery, itself the first major branch of the internal carotid artery.

To assess the external carotid artery system for comparison, the time taken for the pulse wave to travel to the frontal branch of the external carotid artery from the common carotid artery was measured. The frontal artery is a branch of the superficial temporal artery, which is itself a major branch of the external carotid. To obtain a normalizing factor to allow for the influence of systemic blood pressure and the effects of age, the pulse wave transit time between the common carotid artery and the brachial artery was also measured on both sides. This arterial segment was chosen on the basis that it was essentially of a similar length to those under primary investigation. In our experience it is quite common to have unilateral or bilateral external carotid artery disease or subclavian artery disease, but it is extremely rare to have both external carotids and both subclavians diseased in the same patient. We therefore chose the shortest transit time from these segments as being the normal for the patient.

All pulse wave transit times were measured using two continuous wave ultrasonic Doppler velocimeters. A 5-MHz system was used on the common carotid and a 10-MHz system on the peripheral vessels. In order to standardize the probe position in relation to the common carotid, the proximal end of the pencil probe was rested on the medial end of the clavicle. The supraorbital artery was insonated at the supraorbital ridge with the probe pointing away from the eye. The frontal artery was insonated at the level of the supraorbital ridge in the temporal fossa. Finally, the brachial arteries were insonated 3 cm above the medial epicondyle of the humerus. Two observers were required, one for each Doppler system.

The outputs from the Doppler velocimeters were fed to a two-channel real-time spectrum analyser (Stevens and Roberts, 1976). This analyser is of the time-compression type which does a complete spectral analysis every 10 ms between 0 and 5 kHz or between 0 and 10 kHz. The output from the analyser is fed to a fibreoptic recording oscilloscope to give a hard-copy sonogram.

The sonogram tracing correlates the Doppler shift frequency (in kHz) on the ordinate against time on the abcissa, with darkening corresponding to spectral density. Since the Doppler shift is directly proportional to the blood velocity, the sonogram trace effectively shows the velocity wave at that site in the arterial tree.

Fig. 1 shows a typical two-channel sonogram. On the lower line is the common carotid sonogram and on the upper line the supraorbital sonogram. The pulse wave transit time is measured as the time interval between the foot of the systolic upswing of the carotid sonogram and the corresponding point on the supraorbital sonogram. The illustration does not adequately illustrate the grey scale definition available from the recordings, and the spatial resolution of the transit time is better than suggested by the illustration. In practice, when both observers have obtained optimum signals from the two Doppler velocimeters the sonograms are printed out simultaneously on to the same ultraviolet-light-sensitive paper, and a minimum of ten consecutive pulses recorded.

The recordings were analysed with the aid of a Hewlett Packard desk-top calculator interfaced to a digitizing platen, the spatial resolution of which was 0·25 mm. Supraorbital sonograms are often difficult to interpret and the restrictions imposed by the sonogram analyser meant that the overall temporal resolution of the measurements was ±5 ms. Each patient's transit times were measured by three independent observers. Each individual pulse was measured three times and ten pulses were measured for each arterial segment. An average was then taken of all the transit times to obtain mean values for each segment. Thus at the end of the investigation each patient ended up with six mean transit times—two supraorbital, two frontal and two brachial.

Results

A total of 40 carotid arteriograms was performed. Of these, 9 were found to be unsatisfactory in that the degree of stenosis could not be determined. There were no exclusions on the basis of inadequate ultrasonic data. The variability of the transit time measurement obtained from any segment was found to be less than 11 per cent, and this figure includes both the intra-beat variation, the intra-observer variation and the variability of each repeated observation. The mean values of transit times varied from 17 to 124 ms.

Fig. 2 shows the results of plotting the common carotid to supraorbital transit time against the percentage diametral stenosis in the internal carotid. The correlation is only moderate ($r = 0{\cdot}68$, $P < 0{\cdot}001$).

In order to compensate for the effects of age, blood pressure and any bilateral carotid disease on a measured absolute transit time, the supraorbital transit times were divided by the shortest or either the frontal or brachial transit times for each patient for the reasons discussed previously. The transit time ratios were then plotted against the percentage diametral stenosis and the result is shown in *Fig*. 3. Here the correlation coefficient is better ($r = 0{\cdot}8$, $P < 0{\cdot}001$).

e potential

int three gro

pa

1. These with a d

or greater (which

ese et al., 1970] to produce sign

mic disturbance).

2. Minimal disease: Those with a diam 20 per cent or less (which is the degree to be expected of a 'normal' patient of an age to those in our study [Rutherford et al., 1977]).

3. Moderate disease: The remainder, i.e. those with a diametral stenosis between 21 and 50 per cent.

Fig. 4 shows the results of this classification. On the vertical axis is the normalized transit time ratio and on the horizontal axis are the three groups of patients. The mean transit time ratio for stenoses of 51 per cent or greater was $2{\cdot}98 \pm 0{\cdot}56$, that for stenoses between 21 and 50 per cent was $1{\cdot}90 \pm 0{\cdot}47$ and that for stenoses of 20 per cent or less was $1{\cdot}35 \pm 0{\cdot}32$. Assessment with the Student t test reveals a significant difference between the moderately and minimally diseased groups ($0{\cdot}001 < P < 0{\cdot}005$) and between the moderately and severely diseased groups ($P < 0{\cdot}001$).

Discussion

There are several possible explanations of the increasing transit time with stenosis. The foot-to-foot transit time gives an unambiguous measure of pulse wave velocity only where the velocity wave form does not change as it progresses along the arterial system. However, in practice it changes in response to reflections, branching and tapering of the arterial tree. In addition, high frequency components of the wave are attenuated by stenosis (Womersley, 1958). Since the high frequency components tend to travel faster than the low frequency components, their attenuation leads to an apparent increase in the transit time.

As the distensibility of arteries becomes less, as it does with ageing, so the pulse wave velocity will increase. Furthermore, vessels become less distensible as they are stretched. If the pressure in an artery increases, there is a decrease in distensibility and a corresponding increase in pulse wave velocity. Conversely, if the pressure in an artery decreases, then distensibility increases and there is a fall in pulse wave velocity. Carotid arteries have been shown to be among the most distensible arteries in the body (Caro et al., 1978) and pressure drops (caused by local stenoses) of the order of 80 mmHg have been found in the carotids during carotid endarterectomy (Roberts, 1978), for example, from 130 mmHg in the common carotid to 50 mmHg in the internal carotid. This drop would lead to a tripling of the transit time in the artery distal to the stenosis (King et al., 1972).

All these factors help to explain the apparent decrease in pulse wave velocity with increasing carotid artery stenosis and explain why lesser degrees of stenosis are detectable by this technique compared with any other non-invasive technique.

We have demonstrated that there is a prolongation of both the absolute transit time and the transit time ratio with increasing internal carotid artery stenosis, but the work is of little value unless the measurement can be used predictively. In this respect the prognostic value of a transit time ratio of greater than 2·75 is approximately 85 per cent correct in predicting ut la e in pr sten of compares y favou ly wi asive techniques.

Conclusion

We have demonstrated that the transit time ratio can differentiate between minimal, moderate and severe disease. We feel that this technique is particularly useful as it only takes a few minutes to perform, it can be performed by technical staff after minimal training and it is completely non-invasive.

This technique can be used in a variety of clinical problems—evaluation of the asymptomatic bruit, assessment of bilateral stenosis to help decide which side to operate on first, monitoring of patients post-operatively both immediately and in the long term, evaluation of ambiguous neurological or cerebrovascular symptoms, screening of carotid arteries before major abdominal vascular procedures and for screening young patients with evidence of other arterial disease. Further studies are now being undertaken to evaluate this technique for monitoring patients both in the immediate postoperative period and on a long term basis.

We conclude that measuring the pulse transit time ratio is a valuable non-invasive technique for diagnosing and monitoring patients with extracranial carotid artery disease.

Radiological assessment of nipple-valve insufficiency in Kock's continent reservoir ileostomy

C.-G. STANDERTSKJÖLD-NORDENSTAM, [illegible] PALMU AND A. SIVULA*

SUMMARY

In a series of 51 continent reservoir ileostomies nipple-valve insufficiency developed in 15 patients who were examined radiographically to find the cause for the loss of continency. The radiological diagnosis was confirmed at reoperation. The causes for nipple-valve insufficiency were a total or partial disappearance of the nipple-valve by sliding of the invaginate (7 cases) and dislocation of an undamaged nipple out of the reservoir (8 cases). In these groups the radiological diagnosis was compatible with the operative findings in all but one case. At reoperation a fistula in the nipple-valve was found in 3 cases, but in no instance had this been diagnosed radiologically. A correct preoperative diagnosis is valuable, especially in cases of dislocation, where a danger exists that the real mechanism of valve insufficiency may remain obscure at operation.

NIPPLE-VALVE insufficiency is a recognized complication of Kock's continent reservoir ileostomy (Kock, 1976). In a previous paper two of the present authors reported results from 51 operations and nipple-valve insufficiency developed in 15 of these (Palmu and Sivula, 1978). At reoperation two different mechanisms causing insufficiency were found: disappearance of the nipple-valve by sliding of the invaginate (7 cases) and dislocation of an undamaged nipple out of the reservoir (8 cases). Furthermore, a fistula at the base of the nipple was found in connection with partial sliding in 1 patient and in connection with dislocation in 2 patients. Before reoperation the ileostomy reservoir and nipple-valve were examined radiologically. During the course of the series a specific radiological examination technique was developed to find criteria on which a preoperative diagnosis of the mechanism causing nipple-valve insufficiency could be made.

Patients and methods

In 1972–7 a continent reservoir ileostomy was created in 51 patients. Of these, 15 developed nipple-valve insufficiency, most often within 3–6 months of operation. The nipple-valve insufficiency manifested as difficulties in catheterization of the reservoir and spontaneous leakage of gas and bowel contents. In an attempt to elucidate the reasons for these disturbances radiological examinations were performed preoperatively and the results were compared with the findings at reoperation.

Radiological technique

The procedure is performed as a double-contrast study in order to visualize the nipple-valve properly.

1. The ileostomy is catheterized with the same type of large bore (10 mm outer diameter), rather stiff catheter that the patient uses for emptying the reservoir (ileostomy catheter, Medena M 8730, Astra-Sjuco AB). The reservoir is then filled, through the catheter, with ordinary barium contrast medium until the distal end of the ileum is full.

2. The barium is then emptied through the same catheter and air is insufflated.

3. Pictures are taken with the catheter still in the valve in (1) the anteroposterior position and (2) in the left anterior oblique projection, tangentially to the valve.

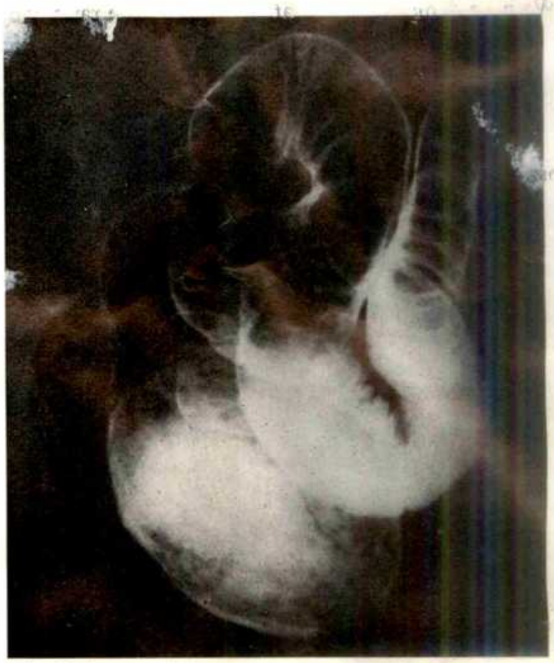

Fig. 1. The normal ileostomy reservoir seen in the anteroposterior view. The nipple-valve is not adequately demonstrated in this projection.

4. More air may be insufflated and the catheter is withdrawn. The tangential pictures are repeated (1) with the patient at rest and (2) with the patient straining.

Results

Radiological findings

Whilst at rest and also when straining, the normal nipple-valve protruded symmetrically 3–5 cm into the internal ileostomy pouch and retained its size and shape both with the catheter introduced and without the catheter (*Figs.* 1 and 2).

When sliding damage to the nipple-valve was present, catheterization was often difficult. When it succeeded no nipple-valve could be seen in the ileostomy pouch. Without the catheter the efferent channel often appeared tortuous and elongated as a result of malpositioning of the bowel which had become loosened from the invaginated nipple by sliding. In partial sliding a short and/or asymmetrical nipple-valve was seen (*Figs.* 3 and 4).

Dislocation of the nipple was characterized by a normal nipple-valve at catheterization, but disappearance of the nipple when the catheter was withdrawn

* Radiographic differential diagnosis between dislocation and sliding was more difficult than usual because the catheter could not be properly introduced through the nipple–valve.

and the patient strained. The nipple was often easily repositioned with the catheter (*Fig*. 5).

No fistulas could be identified radiologically.

Operative findings

When sliding of the invaginate had occurred, there was no nipple to be found in the opened reservoir at reoperation. It had disappeared by loosening of the invaginate and the loosened part of the bowel had escaped from the reservoir forming a tortuous and elongated outlet segment. In some cases the sliding was partial and there was a short stub or a semicircular fold in the reservoir, both remnants of the previous nipple–valve.

[illegible]

[illegible]sion

[illegible]echnique used in patients in this series [illegible]ted by practical considerations. Simple [illegible] [illegible]re of a child's colostomy is difficult in that there [illegible]ually much more oedema and hypertrophy of the [illegible]el mucosa at the site of the colostomy than in [illegible]ts: resection of bowel either side of the colostomy [illegible]s much more satisfactory material to suture. The [illegible]tively thin abdominal wall in children and the [illegible]ence of a skin, or skin and muscle, bridge makes [illegible]aperitoneal closure a difficult or even impossible [illegible]position. Finally, a single-layer anastomosis was [illegible]d in infants because it was thought that a standard t[illegible]-layer closure would unduly compromise the e[illegible]ctive lumen of the anastomosis.

[illegible] is, of course, impossible to make direct comparison between the results of these techniques applied to children and the results of various techniques reported in adult practice, but we feel that our results are acceptable in terms of the incidence of major complications. It is doubtful whether the incidence of such complications could be much reduced, except by emphasizing the importance of excluding distal obstruction, Hirschsprung's disease in particular, before closing a child's colostomy, even though such an obstruction need not necessarily lead to anastomotic breakdown. Possibly more of the faecal fistulas [illegible] conservatively, [illegible] peritonitis, re[illegible] probably the more [illegible]

[illegible]ion, this being [illegible]rted series of [illegible]son why this [illegible]d information [illegible] appears that [illegible]ration reduces [illegible] Of the factors [illegible]provement (i.e. [illegible]n and different [illegible] use of metro[illegible] [illegible] to reduce the incidence [illegible] in colonic surgery (Willis et [illegible] [illegible]portant.

Closure [illegible] id en

A. M. K. RIC[illegible] [illegible] MAN*

SUMMARY

A retrospective sur[illegible] closures in infants [illegible] operative technique consisted [illegible] anastomosis, usually as a sin[illegible] toneal closure. Faecal fistula [illegible] there were other major comp[illegible] Wound infection occurred in 4[illegible] use of a more aggressive bowel pre[illegible] uced the incidence of this complication.

In adult patients closure of a temporary colostomy is a common surgical procedure, and, outside centres specializing in colorectal surgery (Thomson and Hawley, 1972), there is a high reported incidence of major complications, such as faecal fistula (Knox et al., 1971; Wheeler and Barker, 1977) and incisional hernia (Finch, 1976). Temporary colostomy in a child is comparatively rare, Hirschsprung's disease and some types of imperforate anus being the commonest indications for the procedure. However, many colostomies are closed in centres specializing in paediatric surgery, and we present here the results from one such centre because the techniques employed differ in some respects from those generally used in adult practice.

Patients and methods

This comprises a retrospective study of 100 consecutive colostomy closures from January 1969 to May 1978. Only those cases in which a colocolic anastomosis was performed are included. There were 71 male and 29 female patients. The indication for the colostomy was imperforate anus in 47 cases, Hirschsprung's disease in 34 cases, neonatal necrotizing enterocolitis in 7 cases and miscellaneous reasons in the remaining 12 cases. Eighty-five colostomies were of the loop type brought out over a skin, or skin and muscle, bridge and 15 were split (defunctioning) colostomies. The site was the right transverse colon in 49, the left transverse colon in 4, the descending colon in 3 and the sigmoid colon in 44 instances. By virtue of the primary pathology, the series is biased towards infancy, 58 patients being under 2 years of age at the time of colostomy closure.

No bowel preparation was given before closure in 6 patients, but the remainder received some form of preparation. Before 1975 this consisted of mechanical preparation of the distal colon and chemotherapeutic preparation of the proximal colon with an oral, non-absorbable sulphonamide; this was used in 69 cases. From 1975 onwards a more radical preparation was employed, adding mechanical preparation of the proximal colon, by the use of a low residue diet and magnesium sulphate, and chemotherapy of both the proximal and distal colon with orally and stomally administered gentamicin and metronidazole; 25 patients received this preparation.

No colostomy was closed less than 3 months after formation, nor less than 1 month after a definitive procedure to deal with the primary pathology. The operative technique consisted of circumcising the colostomy and mobilizing it into the peritoneal cavity. Between 2 and 4 cm of colon were resected on either side of the colostomy and an end-to-end anastomosis performed, as a single layer of inverting silk or Dacron mattress sutures in 83 cases and as a double layer (all layers chromic catgut, seromuscular silks) in 17 cases, all over 2 years of age. The colon was returned to the peritoneal cavity and the wound closed in layers. Drains, usually placed subcutaneously rather than intraperitoneally, were employed in 72 cases.

Results

Major complications

There were no deaths in this series. Five patients developed a faecal fistula, 3 following closure of a transverse colostomy and 2, a sigmoid colostomy. A single-layer anastomosis had been used in 3 c[illegible]es ar[illegible] bowel preparation given in 4 cases. A drain [illegible] d b[illegible] used in every case. In 4 cases there was n[illegible] obv[illegible] reason for the fistula formation, but in 1 ca[illegible], w[illegible] the colostomy had been performed in the neon[illegible] period for a colonic perforation, it was closed in [illegible] presence of unsuspected Hirschsprung's disease [illegible] the resulting distal obstruction was presum[illegible] responsible for the anastomotic leak. One of [illegible] fistulas closed spontaneously, whilst another spo[illegible]taneously re-formed the colostomy. In the remai[illegible] 3 cases there were signs of local peritonitis, and it [illegible] felt advisable formally to re-establish the colostomy.

Anastomotic strictures occurred in 2 patients, 2 and 3 weeks postoperatively. At re-exploration, in both cases, small bowel was found to be densely adherent to the anastomosis, suggesting the possibility of a previous anastomotic leak.

Other forms of postoperative obstruction were encountered in 4 cases. Two were due to ileal adhesions secondary to previous surgery. Two other patients had unsuspected Hirschsprung's disease (at the time of their colostomy closure they had been erroneously diagnosed as having 'immature bowel' syndrome). When they were re-explored 2–3 weeks postoperatively, the anastomoses were intact despite the presence of gross colonic distension. (In the same respect there were a further 3 patients who ultimately proved to have residual Hirschsprung's disease following the original pullthrough procedure, but when their colostomies were closed in the presence of this residual disease, although they were distinctly constipated in the postoperative period, none showed evidence of an anastomotic leak.)

The single cases of burst abdomen and incisional hernia were both associated with a faecal fistula.

Minor complications

Wound infection: Patients were regarded as having had a wound infection if there was a record of a purulent discharge or a positive bacterial culture from the wound. Excluding the 5 cases of faecal fistula, where the term has little meaning, wound infections so defined occurred in 43 patients (45 per cent). Of the factors that might be implicated, the site of the colostomy, the age of the patient and the use of drains were immaterial, but the more recent method of bowel preparation was associated with a reduced incidence of wound infection—4 infections in 25 cases (16 per cent).

Other minor complications: Ileus was rare. Excluding the 13 cases with major complications, only 8 patients required intravenous fluids 4 or more days postoperatively. Prolonged postoperative hospital stay was common. Of the 87 cases without a major

Melan[illegible]a [illegible] nipple [illegible]ola

D. N. PA[illegible] [illegible]IRI, [illegible]. KINNE[illegible] [illegible] RI AN[illegible]

SUMMARY

Fourteen primary mela[illegible] [illegible]ing in the nip[illegible] areola of the bre[illegible]st we[illegible] [illegible] by mastecto[illegible] axillary dissectio[illegible]. Fou[illegible] [illegible] had axillary node metastases and all [illegible] [illegible]d within 3 y[illegible] their operation, while the [illegible] [illegible]nts with no [illegible] node involvement were fre[illegible] [illegible] recurrent di[illegible] years after their operation. [illegible] [illegible]sis of clin[illegible] anatomical studies, it is sugg[illegible] [illegible]hat a [illegible] excision wi[illegible]out mastectomy i[illegible] [illegible]at for [illegible]ment of nipple and areola m[illegible].

Malignant melanoma of the breast is rare and it is doubtful if a primary melanoma of the nipple has been reliably reported (Haagensen, 1971). Because these tumours are extremely rare, and merge into the brown pigmentation of the nipple, diagnostic delay is probable. This report describes 14 cases of proved malignant melanoma of the nipple and areola.

Patients

From May 1951 to May 1971 115 patients with cutaneous melanoma of the breast were admitted to the Memorial Hospital, New York. Thirty-four of these patients were female and 81 were male. Fourteen patients had primary melanoma arising in the nipple and areola of the breast. Four of these 14 lesions were on the nipple and 10 were in the areola. Two of the patients were female, both of whom had nipple melanomas, and 12 were men. Their median age was 32 years (range 28–62 years). All patients were regularly followed up until 1978.

Results

The incidence of nipple and areola melanomas among cutaneous melanomas of the breast was 12 per cent. The main symptom was 'a mole in the breast' (11 of the 14 patients). Three patients, 2 of whom were female, complained of nipple discharge and/or bleeding. Three patients noted 'moles which had changed' while 8 patients noted the appearance of new lesions on their nipple or areola 4–11 months before their first consultation. The average delay between the patient noting the lesion and the first consultation was 8·4 months. The diagnosis was not made at the first medical examination on 5 occasions, despite the melanomas being of characteristic appearance; 2 of these 5 patients had palpable axillary nodes.

Classification of malignant melanomas by the criteria of Clark et al. (1969) was not started in this institution until 1972. However, retrospective microstaging was possible in 9 patients. Three patients had level IV melanomas, 2 of whom had axillary node metastases, while all 5 patients with less invasive lesions (level III and level I) had no involvement of the axillary lymph nodes.

Nine patients were treated by a radical mastectomy, 4 patients by a modified radical mastectomy and 1 patient underwent an extended radical mastectomy that included internal mammary node dissection in combination with the radical mastectomy. The results of treatment were mainly influenced by the presence or absence of axillary node metastases and not by the type of mastectomy. All 4 patients who had axillary node metastases succumbed to their disease within the third post-mastectomy year. Three had been treated with a radical mastectomy and 1 with a modified radical mastectomy. In contrast, all 10 patients with no metastases in the axillary nodes survived free of disease beyond the fifth postoperative year. The only patient subjected to extended radical mastectomy had no metastases in the internal mammary nodes and survived, with no evidence of recurrent disease 10 years following the operation.

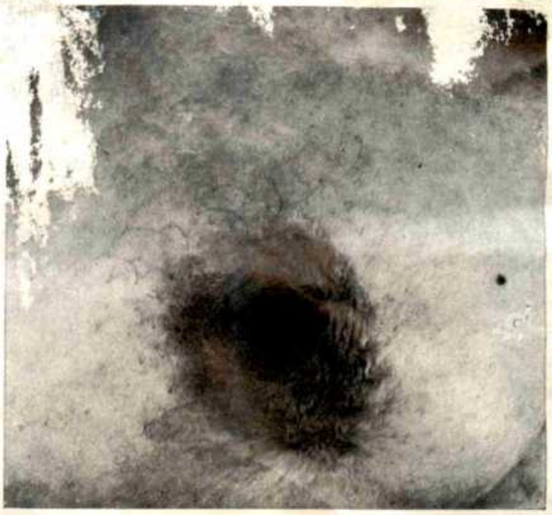

Fig. 1. Melanoma arising in the nipple.

Nipple and areola melanomas demonstrated a better prognosis and a lower incidence of nodal metastases than cutaneous breast melanomas in general. Melanomas arising in the skin of the breast gave rise to axillary metastases in 60 per cent, while only 28 per cent of areola and nipple lesions metastasized to the axillary nodes. The difference is statistically significant ($P<0{\cdot}01$, χ^2 test). Nipple melanomas had a particularly favourable course. All the 4 patients with primary nipple lesions had negative nodes, including 1 patient with a level IV tumour. All remained free of disease at the end of the follow-up period.

Discussion

Malignant melanomas of the nipple and areola are rare neoplasms (Haagensen, 1971). Surrounded by a deeply pigmented skin and covered by the clothes these lesions can escape early diagnosis. Such lesions must be differentiated from Paget's disease, seborrhoeic keratosis and benign moles; this can be accomplished only by histological examination of an excision

[illegible] he oeles [illegible] om [illegible] de tre year. [illegible] ly pi [illegible] een [illegible] n the [illegible] e the [illegible] le and [illegible] gical excision, [illegible] that the [illegible] f distant sprea[illegible]. The inclusio[illegible] xillary [illegible]nph nodes in the dissection fo[illegible] ccepted principles of the treatment of breas[illegible] None of these patients was classified by mic[illegible] (Clark et al., 1969), but retrospective mic[illegible] was possible in 9 patients, 3 of whom had [illegible] nelanomas, with 2 of these 3 patients havin[illegible] ode metastases. Current concepts in regard [illegible] licy of elective node dissection have recently [illegible]n [illegible]sented (Fortner et al., 1977). On the basis of [illegible]is [illegible] and with accurate microstaging of the [illegible]ma, routine axillary clearance may not always [illegible]sary, as the 5 patients in this series with less [illegible] lesions had no axillary metastases, and were [illegible]ore than 5 years after their original operation.

[illegible]e lymphatic drainage of the breast was at first [illegible]sidered to be to the areola, and from the subareola [illegible]xus to the axillary lymph nodes (Grand et al., 1953). [illegible]owever, it is now accepted that the axillary nodes [illegible]ceive all lymph from the subcutaneous and the sub-[illegible]reola plexus, while the deep parenchymal ducts [illegible]irect the lymph from the mammary glands to the [illegible]xillary and internal mammary lymph nodes (Turner-Warwick, 1959; Halsell et al., 1965). It is probable that there is no communication between the subcutaneous lymphatics and those in the breast; thus,

[illegible]d for a mast[illegible] [illegible]ast skin is r[illegible] [illegible] patients in [illegible] [illegible]aries were [illegible] [illegible]oination w[illegible] [illegible] was [illegible] h [illegible]

[illegible] treat[illegible] is [illegible] effe[illegible]ve treatment [illegible] (Landes and Leonhardt, 1967). Sclerotherapy was first used in [illegible] thirteenth century (Landes and Leonhardt, 1967) but has largely been abandoned, probably on poor evidence (*British Medical Journal*, 1973). Maloney's (1975) recent report demonstrated that sclerotherapy could be an effective form of treatment for hydrocoeles and epididymal cysts. This paper reports the results of a prospective study of sclerotherapy undertaken in Leicester.

Patients and methods

Patients

Fifty-six patients over the age of 40 with single or bilateral hydrocoeles or epididymal cysts and without an ipsilateral inguinal hernia were accepted for treatment between January 1976 and July 1977. Eleven were eventually excluded; 6 of them required surgery (4 because of a bloodstained tap and 2 because the swelling did not transilluminate) and 5 failed to complete follow-up (3 failed to attend and 2 died of unrelated causes).

Method

The scrotum was transilluminated to confirm the diagnosis and locate the testis and an 18-gauge Medicut was inserted into the upper border of the hydrocoele or cyst under local anaesthesia. A Medicut was used because a plastic cannula is less likely to traumatize the sac lining and is unlikely to slip out when aspirating fluid or injecting sclerosant. The fluid was fully aspirated using a 50-ml syringe and the volume recorded, after which the testicle was carefully palpated. The sclerosant used in this study was 2½ per cent phenol in water. The volume inserted depended on the volume of aspirate. Five millilitres were used in a sac containing up to 50 ml of fluid, 10 ml for a sac containing 51–200 ml, 15 ml for a sac containing 201–400 ml of fluid and 20 ml of 2½ per cent phenol for a sac containing more than 401 ml of fluid. To ensure complete emptying of the sac sclerosant fluid was swilled in and out before the chosen volume of sclerosant was inserted.

Patients were warned that some fluid might reaccumulate and they were seen at 6-weekly intervals when the scrotum was again aspirated and injected as before, unless (*a*) the aspirate was darker than on the first visit or (*b*) the fluid volume was much less. This treatment was repeated until the fluid no longer reaccumulated. Patients were checked again 3 months later and then contacted at 6-monthly intervals. Doubtful cases were seen again in the clinic.

Results

Out of a total of 36 hydrocoeles, 1 has persisted after four injections but is still under treatment, which was interrupted by two myocardial infarctions. One hydrocoele has recurred a year after completing the initial course of treatment.

[illegible]YDROCOELE: [illegible]ETAILS OF TR[illegible]

[illegible]	No.*	No. of times injected (mean and range)	No. of times aspirated after initial treatment (mean and range)	[illegible] of OP visits (mean a[illegible] range[illegible]

Table II: EPIDIDYMAL CYSTS: DETAILS OF TREATMENT

Size of original aspirate (ml)	No.	No. of times injected (mean and range)	No. of times aspirated after initial treatment (mean and range)	Tota[illegible] no. of visits (mean a[illegible] range)
0–50	8	1·1 (1–2)	1 (0–2)	2·9 (2–4)
51–200	4	1·8 (1–3)	2 (1–3)	4·5 (4–5)
201–400	1	4	6	7

Table III: HYDROCOELES ASPIRATED MORE THAN TWICE BEFORE COMMENCING TREATMENT

Patient	No. of times aspirated	Frequency (mth)	Size (ml)	Cured (yr)
A	30	6	350	1¼
B	3	3	150	1¼
C	17	4	500	1½
D	5	3–6	200	2
E	8	3	270	1¾
F	20	6	550	1
G	50	3	260	1¼
H	20	3–6	750	1½

Table I shows details of the treatment required and the total number of outpatient visits in relation to the original volume of fluid aspirated. On average, the larger the hydrocoele the longer the course of treatment.

Treatment details of sclerotherapy for epididymal cysts are shown in *Table II*. The cysts tended to be smaller than the hydrocoeles and responded to treatment more readily. The distinction between hydrocoeles and epididymal cysts was necessarily made purely on clinical grounds and is open to some inaccuracy.

Table III illustrates the results of sclerotherapy in an important group of 8 patients who had been refused operation on grounds of ill health and had been attending the outpatient department every 3–6

---

[illegible] roc[illegible] than 1[illegible] [illegible] nsation [illegible] fossa whi[illegible] was being injected. Two patients comp[illegible] ticular tenderness which lasted from 1 to 2 [illegible]

Six patients developed some degree of pa[illegible] thickening of the tunica vaginalis and epididymis; all of these patients had a hydrocoele greater than 250 ml which eventually became smaller so that the testis and epididymis were only slightly larger than on the other side. Two other patients have a residual swelling; one patient, who originally had a 475 ml hydrocoele, has a fibrous swelling above the testis about the size of a 50 ml epididymal cyst, and the other, who originally had a 550 ml hydrocoele, has a residual fibrocystic swelling approximately the size of a 100 ml hydrocoele. No patient has developed an infection.

Discussion

The results of this study show that sclerotherapy in the treatment of hydrocoeles and epididymal cysts is effective and free from all but minor side effects, and in 98 per cent of cases does not recur within an average follow-up of 18 months. These findings are comparable to those reported by Maloney (1975), who used a slightly different sclerosing agent.

At present the standard treatment of hydrocoeles and epididymal cysts is either repeated aspiration or operation (Pender, 1973; Whitaker, 1976; Rains and Ritchie, 1977). The former is not curative (*Table III*) and the latter has a high incidence of complications (Maloney, 1975). These can be minimized with careful surgery (Lord, 1964, 1970), but the development of a postoperative scrotal haematoma is notorious.

In conclusion, the present author would recommend surgery for fit patients under the age of 40, those suspected of having a testicular tumour and those with a hydrocoele greater than 500 ml. All patients refused operation on the grounds of ill health should be treated with sclerotherapy and for the remainder sclerotherapy is recommended but operation could be offered as an alternative.

Acknowledgements

I am grateful to the consultant surgeons of the Leicester Royal Infirmary and Leicester General Hospital who kindly referred their patients for treatment.

The ingrowing [illegible] [illegible]lifie[illegible] matrix excision [illegible]

S. S. GABRIEL, V. DALLOS A[illegible] J E [illegible]ENSON*

SUMMARY

A series of 528 patients with ingrowing toenails has been operated on under local anaesthetic by one surgeon using a simple technique in which a segment of germinal matrix is completely excised without cutting skin and with minimal interference with the nail wall. Normal footwear was worn by the fifth day in 79 p[illegible] of patients. The recurrence rate was [illegible] per cent.

INGROWING toenail is a common condition in the United Kingdom which causes the loss of many days from work by young adults. Lack of appreciation of the pathology of this condition has resulted in a large number of treatments which range from the wholly conservative approach (Lloyd Davies and Brill, 1963) to amputation of the distal part of the terminal phalanx (Thompson and Terwilliger, 1951; Rees, 1964; Townsend and Scott, 1966). In addition, there exist many operations which lie between these two extremes (Quènu, 1887; Watson-Cheyne and Burghard, 1912; Ney, 1923; Winograd, 1929; Heifetz, 1945; Zadik, 1950; Fowler, 1958; Palmer and Stevenson, 1976).

We believe that any operation for ingrowing toenail should satisfy the following criteria: the recurrence rate should be minimal; normal footwear should be worn with comfort within a week of the operation; a painless nail-bearing toe should be the end result; finally, the procedure should be simple.

An operation which satisfies these criteria has been developed by one of us (S. S. G.) and this paper gives details of the technique together with the results obtained in a series of 528 consecutive patients.

Patients and methods

A total of 528 consecutive patients with ingrowing toenails, attending the Accident and Emergency Department of Whipps Cross Hospital, London, over a 3-year period, was operated on by one surgeon (S. S. G.) using the technique described below. The age incidence is shown in *Table I*. Out of the series, 358 patients (68 per cent) were men and 170 (32 per cent) were women; 25 patients (4·7 per cent) were non-Europeans. In all cases it was the big toe that was affected and details of siting are shown in *Table II*. Twenty per cent (107) of the patients had previously undergone an operation for ingrowing toenail on one or more occasions. No antibiotic cover was used. Bilateral cases were treated on separate occasions.

The patients were followed up by a different doctor (V. D.) with the late results being assessed by a postal questionnaire 6 months to 3 years after the operation. If there was a recurrence the same operation was performed again.

The operation

The operation is performed using a local anaesthetic ring block of 3–5 ml of 1 per cent lignocaine without adrenalin.

A McDonald's dissector is introduced beneath the middle of the free edge of the nail and inserted as far as the lunular line. Keeping close contact with the undersurface of the nail, it is moved slowly from side to side, a manoeuvre which completely separates the nail from the nail bed. The nail is then gripped with artery forceps and removed with a gentle rolling motion.

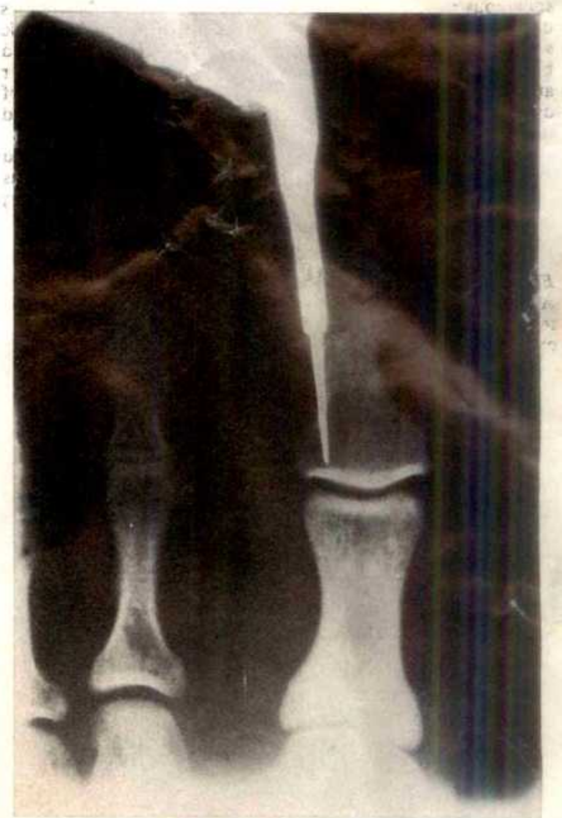

Fig. 1. Radiograph showing the scalpel incision into the nail bed and germinal matrix extending almost to the terminal interphalangeal joint.

A number 11 scalpel blade is used to make a longitudinal incision through the whole thickness of the nail bed and germinal matrix, marking out a narrow strip of tissue on the affected side about a quarter of the width of the germinal matrix and nail bed. The proximal limit of the incision in the matrix should be halfway between the lunular line and the terminal interphalangeal joint (*Fig.* 1). The nail fold is not incised and in order to facilitate the last part of the incision the nail fold is gently elevated on the back of the scalpel blade. The strip of tissue to be removed has now been clearly identified.

Small curved scissors are used to dissect the strip of tissue off the periosteum of the phalanx. The dissection starts distally with a small snip of the scissors at right angles to the initial incision. As the dissection proceeds, the strip of tissue is held by forceps and gently elevated until the point midway between the lunular line and the interphalangeal joint is reached. Here, the attachment of the germinal matrix ends so that separation at this critical level takes place naturally. No incisions in the nail fold are made.

The last step is to curette away any granulation tissue and then to excise carefully the epithelium on the inferior surface of

the adjacent nail wall so as to ensure quick healing between the nail wall and the site of the excised nail bed. The number 11 scalpel blade is used for this manoeuvre.

Postoperative treatment

The wound is dressed with paraffin gauze and a pressure bandage applied. The patient is kept in the theatre area for half an hour with the foot elevated and is then sent home with instructions to keep the foot elevated for 24 h. Four days later the primary dressing is replaced by a smaller paraffin gauze dressing and the patient can then in most instances put on normal everyday shoes. At the next appointment, one week later, the patient is told that he can resume normal activities and is advised about the care of the new nail when it grows.

Results

Table III shows that 418 (79 per cent) of the patients returned to wearing their usual shoes within 1 week of the operation.

A total of 409 of the 528 patients completed the postal questionnaire showing late recurrence in 7 cases (1·7 per cent). These patients were recalled for further operation. There was no case of a second recurrence.

Discussion

The recurrence rate and morbidity associated with the surgical treatment of ingrowing toenail by traditional methods is high (Murray and Bedi, 1975) and we believe this series shows that both can be reduced to a more acceptable level. As far as we are aware there is no evidence to suggest that there is any difference in the recurrence rate between operations with complete excision of the germinal matrix and operations with [illegible]tal excision [illegible] mina[illegible]ix. It seems [illegible]erefore, tha[illegible] exc[illegible]s desirable so [illegible]tain the ad[illegible] a nai[illegible]ing toe. [illegible] widely kno[illegible]urre[illegible]ter operation [illegible]kes the forn[illegible]le of [illegible]djacent to the [illegible]all suggesti[illegible]senc[illegible] onychogenic [illegible]at this site. [illegible]re advocate excision of [illegible]ithelium on t[illegible]rface of the nail wall as [illegible]sted by Lapidu[illegible]o as to prevent this form [illegible]currence. Th[illegible]ecurrences recorded here [illegible]t all occurred [illegible]arly on in the series when it [illegible]sible that insu[illegible] care was given to this part [illegible] technique.

[illegible]noval of th[illegible] nail as a first step in the op[illegible]ion facilit[illegible]recise excision of the strip of na[illegible] be[illegible] and [illegible]nal matrix and makes skin incisions unnecessary. This avoids the need for suturing over a potentially infected area and gives a better cosmetic result. Removal of the whole nail also allows for better drainage of any infection that may be present.

A particular advantage of the operation we describe is that it is extremely simple and can therefore be safely undertaken by inexperienced junior staff.

Loop col of colostomy i i

M. M. HENI KWOOD, V. HEMALATH

SUMMARY

The records of 0 consecut co closed at Adde dren is 1975 were stud pulmonary emb fistula from the cent.

A number of di ering 6 weeks after the colos op-tive antibiotic (ant nic obi aration appeared to be factors associa with favourable outcome. On the other hand, initial operation for carcinoma and closure less an 6 weeks after the colostomy's formation were factors related to a less favourable outcome.

THE incidence of complications following colostomy closure varies in different reported series. A high complication rate was reported by Knox et al. (1971) in a study of 179 colostomy closures performed in a major non-university centre, with a leakage rate of 23 per cent. That this operation is not necessarily attended by such a high morbidity rate is suggested by the results from St Mark's Hospital, London (Thomson and Hawley, 1972). In a series of 139 patients these authors reported an incidence of breakdown of only 2·9 per cent at the site of the colostomy closure. These operations were, however, performed by relatively experienced surgeons most of whom had a special interest in colorectal surgery. It is possible, therefore, that the results from the Exeter group (Knox et al., 1971) reflect more accurately the true hazards of the procedure when it is performed in a non-specialist centre. Barron and Fallis (1958) and Finch (1976), however, suggest that this is not necessarily so.

A retrospective analysis of the results of loop colostomy closure performed at Addenbrooke's Hospital was undertaken with two objectives. First, to compare the complication rate of this operation performed at our hospital with that of a specialist centre, and secondly, to assess any factors that may be associated with the development of complications.

Patients and methods

The records of 74 patients with loop colostomies closed during the period 1970–5 were analysed. The majority of these colostomies had been formed as part of a staged procedure in the treatment of distal colonic disease. All involved the transverse colon.

The average age of the patients was 63·5 years and the age distribution is shown in *Table I*. The male/female distribution was 1·7/1. In all cases a barium enema examination was performed before colostomy closure to demonstrate the integrity of the anastomosis and the absence of obstruction. Sigmoidoscopy was performed in some cases but not as a routine. The interval between formation and subsequent closure of the colostomy was less than 6 weeks in 41 patients (55·4 per cent) and more than 6 weeks in 33 patients (44·6 per cent).

The operations were performed by 16 surgeons: 39·2 per cent of the colostomies were closed by 3 consultants, 1 with a particular interest in colorectal surgery. The remainder were closed by registrars of widely differing experience.

ere was considerable variation in technique. All clos e intraperitoneal with drainage of both the anaston d the wound. In 83·8 per cent the ends of the colost ere resected while in the remainder the edges were trim nd the bowel approximated, leaving the posterior wall int reoperative mechanical bowel preparation was carried out ll patients: this included colonic washouts in the 48 h bef surgery. In 14 patients (18·9 per cent) antimicrobial bo preparation with oral phthalylsulphathiazole was also us Approximately 50 per cent of patients were treated w prophylactic antibiotics—tetracycline or penicillin a streptomycin.

The majority (77 per cent) of anastomoses were sutured one layer with interrupted Supramid; interrupted silk was u in 2 cases. The remainder (23 per cent) were sutured in layers using continuous catgut for the inner layer and interrupted silk sutures for the seromuscular layer.

Results

The postoperative course was uneventful in 62 of our 74 patients (83·8 per cent). One death occurred (1·4 per cent) in a 76-year-old man with malignant disease who developed a minor faecal fistula and wound infection. Both resolved spontaneously but the patient died from a pulmonary embolus on the eighteenth postoperative day.

Six patients (8·1 per cent) developed a faecal fistula. Two of these fistulas, however, were from the distal anastomosis rather than from the site of the colostomy closure. Both these patients showed evidence of leakage within 24 h of surgery. One had an extensive collection of pus drained from beneath the original laparotomy wound. The other became septicaemic but responded to a course of parenteral antibiotics and no further surgery was necessary. The intervals between formation and closure of the colostomy in these patients were 3 weeks and 3 months respectively. In both cases a barium enema examination performed before closure showed a small leak which had apparently sealed and an otherwise sound anastomosis.

Only 4 (5·4 per cent) of our patients developed a leak from the site of the colostomy closure. In none was this associated with septicaemia and all the leaks closed spontaneously with conservative management.

In *Table II* the various factors that might have been associated with the development of complications are listed. The group of 4 patients who developed fistulas from the site of the colostomy closure is compared with the majority who did not. Since the number of patients with this complication was small, no attempt was made to draw a statistical comparison.

It is of interest to note that no faecal fistulas developed in those patients whose operations had been performed by a consultant, although nearly 40 per cent of all the colostomies had been closed by a surgeon of this seniority. Similarly, fistulas did not occur in any patient who had received preoperative antimicrobial bowel preparation nor in those whose colostomies had been closed more than 6 weeks after formation. All 4 patients who developed a faecal fistula had had resections for carcinoma and

their colostomies had been closed by the technique involving excision of the bowel ends. It would appear from these results that age, sex, prophylactic antibiotics and one-layer anastomosis are factors that do not influence the incidence of fistulas from the site of closure.

Wound infections occurred in all patients who developed a leak from the site of the colostomy closure. A further 6 patients developed wound infections without the coexistence of a faecal fistula. The various associated factors are listed in *Table III*, comparing these 6 patients with the 62 patients who were free of complications.

Age, sex, prophylactic antibiotics, one-layer anastomosis and the interval before closure do not appear to be factors relevant to the development of wound infection.

in … o the fistula group, 4 of the 6 patients … a wound infection had been operated … t. The groups were comparable, how… f the wound infections occurred in … rcinoma whose colostomies had … ing formal excision f the bowel … nt treated preopera ely with an … aration developed a wound in-

al leakage from the site of … ·4 per cent in our series. This … the figure of 2·9 per cent … k's Hospital (Thomson and Hawley, … 's perhaps explained by the fact that the majority of our cases were operated upon by relatively inexperienced surgeons and that, of the 3 consultant surgeons, only 1 had a special interest in colorectal surgery. The fact that all 4 patients who developed a leak had been operated on by registrars supports this contention. Also, as the St Mark's group admit, there must be some degree of case selection in their series. Their results may not, therefore, be truly representative.

Our results compare favourably with the 9 per cent incidence of faecal fistula reported from Oxford (Finch, 1976) and the 23 per cent incidence from Exeter (Knox et al., 1971). However, a larger number of patients were studied in each of these series.

In addition to the patients who developed a wound infection in association with a faecal fistula, a further 6 patients (8·1 per cent) developed a postoperative wound infection alone. Excluding the 2 patients who leaked from the distal anastomosis, there was an overall incidence of wound infection of 13·5 per cent. This compares with 17·2 per cent from St Mark's Hospital and 33 per cent from the Oxford and 30 per cent from the Exeter groups. Different criteria for assessing the presence of wound infection may account for these differences.

Because of the small number of patients in our series, it is difficult to determine the factors that may be associated with either a greater or a lesser risk of complications following this procedure. However, none of our patients who had been treated preoperatively with an antimicrobial bowel preparation developed complications. Finch (1976) found that the incidence of faecal fistula in patients not having had antimicrobial bowel preparation was twice that seen in the other group. Dixon and Benson (1944) similarly found that the incidence of faecal leakage fell from 30 per cent to 2 per cent in those treated preoperatively with succinylsulphathiazole and sulphathiazole. In this series the incidence of wound infection fell from 84 per cent to 13 per cent following the use of antibiotics, whereas Finch (1976) found the wound infection rate to be similar in the two groups. In contrast, in our series the use of oral or systemic antibiotics did not appear to affect the incidence of wound infection, although only 1 of the 4 patients who developed a leak had been treated preoperatively with antibiotics.

That closure of a colostomy performed within 6 weeks of its creation should be associated with an increased risk of developing a fistula is unexplained. Thomson and Hawley (1972) found a high risk of complications if the colostomy was closed within 28

days and they attributed this to [illegible]
culties created by the early oedema [illegible]
of the colostomy which may occur. [illegible]

The presence of underlying mali [illegible]
a constant factor in all our patien [illegible]
complication. In the St Mark's s [illegible]
who developed a leak at the si [illegible]
closure had all had resections [illegible]
but this was not found to be [illegible]
Finch (1976) similarly found [illegible]
in the complication rates w [illegible]
pathology was benign or m [illegible]
hand, Knox et al. (1971) fo [illegible]
occurred more commonly in [illegible]
ticular disease, although the fig [illegible]
by statistical methods.

None of our patients was recorded as having developed an incisional hernia at the colostomy site, although this was a frequent finding in other series. Although this low incidence may have been due to failure to look for and record this complication, it may also reflect the success of nylon as a suture material for closing wounds, since virtually all the wounds in our series were closed with one layer of continuous double nylon (metric 3). The advantages

s technique:

[illegible]s technique has been used to close 238 abdominal wounds. No dehiscence occurred in this series. It is suggested that this method, which gives strict guidelines on wound closure, is ideal for teaching good technique for wound closure.

In 1976 Jenkins stated that the burst abdominal wound has a mechanical cause, being the result of suture breaking, knot slipping, the intact suture cutting out of the tissues or protrusion of gut or omentum between the sutures (Jenkins, 1976). These factors were considered to be due to the wound lengthening by as much as 30 per cent if distension occurred. It was suggested that wound disruption can be avoided by using a suture length four times as long as the wound, and by placing non-absorbable sutures at 1-cm intervals and more than 1 cm from the wound edge. To test this hypothesis a prospective study was made of 238 consecutive wound closures in 219 patients. These wound closures were performed by the author, or by another member of the junior staff under supervision, between May 1976 and April 1978. The nature of the operations and the incisions used are shown in *Tables I* and *II*.

Pfannenstiel	5

Technique

The incisions were closed with continuous [illegible] nylon (metric 3·5 Ethilon) on a 40-mm round-bodied half-circle needle (Ethicon W 740) using suture length to wound length ratios of greater than 4 : 1 and large tissue bites of greater than 1 cm. The wounds were closed in layers whenever possible. Mass closure was used if the layers were obliterated or if adequate layered bites could not be obtained. Midline incisions were closed in one layer, paramedian incisions were closed in two layers and transverse or oblique incisions were closed in the layers present at the particular site. The peritoneum was closed separately only if this facilitated the muscle closure by reducing the viscera, otherwise it was included with the deepest muscle layer. The nylon suture was tied with a triple-layer surgeon's knot and the ends cut flush with the knot to leave no tails.

Results

All wounds were reviewed at 6 weeks. No wound dehisced during the period of the study, and at 6 weeks there was no evidence of an incisional hernia. None of the 38 patients who died (17·4 per cent) showed a primary wound failure.

Discussion

To gain acceptance any new surgical technique must provide good results in the hands of others. Such techniques should be uncomplicated, easily learned and, if possible, universally applicable without special equipment. The ability to close abdominal wounds is a prerequisite for all surgeons in training before other procedures can be undertaken. Surprisingly, few guidelines are given to the trainee, and these cannot be accurately defined. The technique under consideration has the great merit of providing accurate measurements, which can guide the novice.

This study confirms the results reported by Jenkins (1977) and shows that the technique can be learnt by the trainee, with good initial results. It would seem that this study supports the hypothesis that bursting of the abdominal wound has a mechanical cause; furthermore, dehiscence can be prevented by overcoming this mechanical cause of wound failure.

Discussion

Infection of prosthetic joints is a serious complication of joint replacement surgery and may necessitate removal of the prosthesis and conversion to a Girdlestone pseudarthrosis. Infection may be early or late. Early infection occurring in the immediate postoperative period is usually clinically obvious, but infection occurring several months after surgery may be difficult to identify. Late infection is thought to be due to wound contamination during surgery or to haematogenous spread from a septic focus (Coventry, 1975). Late infection of total hip replacements following haematogenous spread from a septic focus is well documented (Mallory, 1973; Creuss et al., 1975; Downes, 1977), but precise proof of late infection occurring due to contamination at the time of surgery has not yet been produced. In our own patient, it would seem unlikely that the origin of sepsis was contamination of the wound at surgery because both the replacements were carried out in a sterile environment and extensive bacteriological monitoring revealed no organisms. The site of presentation of the infection and the unusual nature of the organism makes it likely that it was caused by haematogenous spread from perhaps a minor focus of sepsis which passed unnoticed by the patient. Indeed, Downes (1977) has made a plea for the treatment of any potential sources of infection before replacement surgery and also after any procedure liable to produce a bacteraemia.

[illegible]ical suspicion that this was no ordinary ischiorectal
[illegible]scess should have arisen earlier as haemolytic *S. pyogenes* is not an organism commonly grown from such abscesses. Indeed Page and Freeman (1977) have found that only 4·7 per cent of perianal suppuration in their series was due to *S. pyogenes*.

It is well documented that colonic or rectal pathology can present with sepsis in the upper thigh or buttock (Main et al., 1977), but we believe that this is the first case of hip sepsis to present perineally. Considering the intimate relationship of the acetabulum to the ischiorectal fossa perhaps it is surprising that it is not more common.

Late infection of a total hip rosthes as an ischiorectal abscess

R. D. BRIGGS, J. MCLAUCHLAN AND A. DAVIDSON*

SUMMARY

Late infection of a total hip arthroplasty recently presented as an ischiorectal abscess. A likely pathogenesis is suggested and the literature on late infection in prosthetic joints is reviewed.

Case report

A 68-year-old lady presented in 1972 with a 4-year history of bilateral hip pain of gradually increasing severity. Clinically, this was attributed to osteoarthritis of both hips and this was confirmed radiologically.

In early 1973, bilateral total hip arthroplasties were carried out, a surgical isolator being used during both operations. Bacteriological monitoring of the wound and environment throughout operation was negative and the postoperative period was uneventful. The patient was discharged from hospital after 5 weeks. She was reviewed in the outpatient department on several occasions over the following 6 months and was discharged in late 1973, pain-free and walking without aid.

In June 1976 she noted vague pain in her right hip, but thought nothing of it. In the intervening period, she had been symptom-free and in excellent general health. She was admitted to hospital late in June 1976 with an ischiorectal abscess which was incised and drained. Culture of the pus obtained produced a haemolytic *Streptococcus pyogenes* (Lancefield Group C). Following this procedure, the pain in her hip appeared to improve, but she continued to discharge pus from the abscess cavity over the following 4 months. This was attributed to a fistula-in-ano, but an examination under anaesthetic failed to delineate the postulated fistulous track. The sinus was explored and curetted on two occasions, but persistently failed to heal.

In December 1976 she was complaining bitterly of pain in her right hip and a radiograph at this time revealed central subluxation of the acetabular component of the right total hip prosthesis (*Fig.* 1).

She was admitted to hospital and the pain improved with conservative measures including bed rest, traction to the right leg and a lumbosacral belt. She was discharged home after 2 weeks but her perineal sinus continued to discharge.

Over the next few months her hip became increasingly painful and she was readmitted in March 1977 for further investigation. An anteroposterior radiograph of her pelvis at time showed central subluxation of the right hip prosthesis was transferred to Aberdeen Royal Infirmary in June 197 with intractable pain in her right hip. On admission she wa cachectic with fixed flexion of her right hip, any movement of which produced excruciating pain. Her haemoglobin was 9·9 g with a blood film suggestive of an iron deficiency anaemia. As she still had a perineal discharge, it was felt that she migh

Corresponden [illegible]

On survival rates in surgical [illegible]

Sir,

K. A. Myers and his co-aut[illegible] Surgical treatment of the sev[illegible] rates. *Br. J. Surg.* **65**, 460–464) [illegible] labours and for adopting the li[illegible] assessing the results. Yet, a clo[illegible] educes some anxiety as to the interpret[illegible] as to any justification for optimism. [illegible]

Inspection of any life survival [illegible]le [illegible] passing of time, the number o[illegible]vive[illegible] mortality theorists have endeavo[illegible] pr[illegible] an 'attrition force' which would exp[illegible]d p[illegible] and the slope of the curve. Recent [illegible] (Strehler and Mildvan, 1960) assumes that there exists a *force of mortality* which tends to displace the individual from the condition of being alive to one of being dead, and that the individual reacts by calling upon his reserves of *vitality* in order to resist this displacement. This vitality (the Gompertz component of Strehler and Mildvan) is an age-dependent function and it diminishes with the passing of time; but the force of mortality is environmental and its strength varies (i.e. the vitality of an individual suffering from a cold would come under attack by a force of mortality not quite as powerful as if he were suffering from meningitis).

By this thinking, one might anticipate that by exposing one of two equivalent populations to an increased force of mortality, then the survivorship curve for the challenged group should show a steady downward displacement (i.e. a reduction in the number of survivors), which should last until the effects of the agency are exhausted, at which time the two curves should assume parallel courses. Experimental evidence from mice exposed to halothane (Boba and Drews, 1966) and the study of life expectancy after diagnosis of cancer of the breast (Mueller et al., 1978) confirm these assumptions.

We may now comment on the authors' figures:

Fig. 7: The survivorship curve for patients with myocardial ischaemia should, and it does, exhibit a divergent downward path from that of patients free of it (the former group being, in fact, exposed to a greater force of mortality).

Fig. 6: Here the same considerations prevail, except that the curves begin to diverge 1 year later.

Fig. 8: After the force of mortality effects specific to each presenting symptom are exhausted, the survival curves follow parallel paths, just as expected.

Fig. 5: The steadily divergent curves from zero time onward would support the assumption that symptomatic leg ischaemia is an agency with an intrinsic and continuous force of mortality. However, this is an artefact secondary to the expansion of the left side of the time scale (once this is corrected one obtains a duplicate of *Fig.* 3).

Fig. 3: The initial sharp fall in the survivorship curve for patients in the study is an effect of the specific force of mortality of symptomatic leg ischaemia *and of the treatment.* This effect lasts about 2 years, and after that time the curves continue to diverge, but *at a much slower rate.*

The following alternate conclusions are now proposed:

1. Symptomatic leg ischaemia indicates a sudden discrete increase in the force of mortality applied to the patient. The curve indicates that its effects *and the effects of treatment* last about 2 years; thereafter these patients continue to be at a somewhat increased risk (probably entirely accounted for by such concom[illegible] diseases as diabetes and myocardial ischaemia, as shown [illegible] 7).

2. There were [illegible]s performed in 411 patients at or about the time [illegible] symptomatic ischaemia. If any of this had been of s[illegible]alue, then the survival curve for patients operated upo[illegible] follow a course parallel to that of the general population, a[illegible]r a short-lasting initial downward displacement because of anaesthetic and operative m[illegible]ity; yet *Fig.* 3 shows that this is clearly not the case.

[illegible]ateria[illegible] [illegible]minate [illegible] ce[illegible] [illegible]e treat[illegible] one d[illegible] [illegible]erapeutic programmes.

[illegible]ould give serious consideration to the [illegible] [illegible]urvivorship alone, better results might be obtai[illegible] [illegible]were directed towards (*a*) early and aggress[illegible] (i.e. reduce the number of anaesthetics and ope[illegible] [illegible]he number of hospital days); (*b*) early ambulatio[illegible] [illegible]ntroduction of necessary changes in life-style (sto[illegible] [illegible]r control of diabetes etc.).

Perforated appendix—a plea for lavage

Sir,

Greenall and his colleagues (*Br. J. Surg.* **65**, 880–882) have investigated the value or otherwise of an intraperitoneal drain in patients with perforated appendix. Over an 8-year period major wound sepsis occurred in 50 per cent of patients in whom a drain was inserted and in 44 per cent in whom drainage was avoided.

The signal benefits of antibiotic peritoneal lavage in gross peritoneal contamination have been established experimentally (Stewart and Matheson, 1978b) and antibiotic lavage of the peritoneal cavity and of the wound in patients with bacterial contamination has been our routine for some 13 years. In 58 children with perforated appendix in whom the peritoneal cavity was washed out with tetracycline in saline, the incidence of purulent discharge from the incision was 8·6 per cent compared with 29·2 per cent in 72 similar children treated during the same 10-year period (1965–74) without lavage (Stewart and Matheson, 1978a).

During 1977 and 1978 we have kept a wound record in all adults under our care in whom operation involved opening the peritoneal cavity. During this 2-year period, excluding patients in whom the appendix was obviously normal, 64 patients were operated on for appendicitis. Lower midline incisions were used in 4 and grid-iron incisions in the remainder. Neither peritoneal nor wound drains were used except in one patient in whom a wound drain was inserted contrary to general policy. All wounds were closed primarily. Wound infection as evidenced by purulent discharge was not recorded during the hospital stay of any of these patients, but one patient, sent home 7 days after a lower midline incision for appendicitis with an established abscess, returned some days later with wound infection. The longest stay in hospital was 10 days after operation and the mean duration of stay was 5 days. It is possible that, unknown to us, wound infection may have occurred in some of these patients after discharge from hospital and, furthermore, the appendix was perforated only in a small minority, so that we do not regard these observations as comparable to those of Greenall et al. (1978). None the less, they strengthen our conviction that neither wound sepsis nor residual intraperitoneal infection need be much of a problem after appendicectomy and that drains are neither necessary nor desirable. In all these patients the peritoneal cavity was washed out locally, usually with about 400 ml of saline containing 1 mg/ml tetracycline, the remainder of the 500-ml

Radiology of the Ear, Nose and Throat

el and Glyn A. S. Lloyd. Second edition. 24
with 330 illustrations. 1978. London: Lewis.

d edition of Samuel's well-known book on of the ear, nose and throat is a very welc the library of the ENT surgeon. The coverage of the ial is very clear and didactic and certainly all the owledge required for those reading for higher examin ons in ear, nose and throat surgery is well covered. The t ould have been improved if the authors had also taken clinical advice about matters beyond their field: at several points statements are made which are either untrue or unfamiliar; for instance, the terms 'intrinsic' and 'extrinsic' carcinoma of the larynx have not been in use by clinicians for twenty years or so.

The book is beautifully produced, easy to read and clearly written, with the exception of the authors' irritating habit of the use of the word visualize; I hope that radiologists see things and do not imagine them!

This book is a classic in its field and is essential reading for the ENT surgeon in training, for the established consultant and for those required to give postgraduate instruction. It should also be an essential part of the library of any district general hospital with a full ENT department.

P. M. STELL

Boies's Fundamentals of Otolaryngology: A Textbook of Ear, Nose and Throat Disorders

Edited George L. Adams, Lawrence R. Boies and Michael M. Paparella. Fifth edition. 230 × 155 mm. Pp. 746 + xix. 1978. Philadelphia: Saunders. £12·50.

THIS textbook, which was first produced in 1949, is now in its fifth edition, nearly 30 years later. It claims to be a standard textbook for medical students and house officers. It also includes, in addition to the standard ENT text, a small section on facial plastic surgery.

One would have to be a devoted student to wish to read so large a text and it is certainly well beyond the needs of any British student taking his final MB examination and compares unfavourably both in detail and cost with simpler textbooks available in paperback. For a house surgeon it would prove a useful source of reference, but again there are simpler texts at a much lower cost. For those wishing to take the final fellowship in ENT it would not be sufficient, but for those taking the DLO it might well prove worth while. As a general comment, the book contains much of solid worth, which is easily assimilated, but several conditions, which many would regard as quite rare, seem to receive an attention which is out of proportion.

For me the biggest disappointment was that in many parts of the book, no approximate statistical information is given as to the prevalence of many of the conditions, thereby guiding the reader as to the emphasis he should place in his reading.

The book is well and simply illustrated, but those reading the section on audiology must remember to consult the key before so doing, as the international range of symbols is not used.

is book recur s ly the proce ings of an international symposium on ulcer e co tis and Crohn's disease sponsored by the Austrian A ion of Paediatric Surgeons in January 1976. Some other p which were not given at the symposium have been incl

There are five s of various forms of treatment of ulcerative colitis, including the use of salazopyrine and steroids and the follow-up results of operations for ulcerative colitis in children, the long term results of medical treatment and a discussion of immunosuppressive treatment in ulcerative colitis in childhood. Another chapter discusses a clinical survey of the symptoms, associated diseases and local and metabolic complications of Hirschsprung's disease and the treatment with various drugs and immunosuppressive agents. Another study considers 19 children and 160 adults with Crohn's disease with particular reference to the features of the disease in children and their management, and it is emphasized that the risk of relapse is greater when the disease involves the ileum and the proximal colon than when it is more distally situated in the colon. A chapter on neonatal necrotizing enterocolitis emphasizes the early onset of this disease; many patients begin to suffer from it within 24 h of birth and the mortality rate remains high, even though the birthweight in this particular series was greater than in most other reported series. Another paper discusses the implications for operation in necrotizing enterocolitis and the type of procedure which is carried out. In addition, there is a chapter on 82 patients with congenital duodenal obstruction, another on portal hypertension, a most interesting paper on the history of malformations of the anus and rectum and another on cystic lymphangiomas infecting various organs within the abdomen.

This series of papers is of interest mainly to paediatric surgeons, to whom it can be recommended.

A. W. WILKINSON

1001 Multiple Choice Questions and Answers in Surgery

A. J. Harding Rains. 197 × 130 mm. Pp. 221 + ix. 1978. London: Lewis. £4·00.

THIS collection of MCQs in sur y was obviously designed as a revisional exercise on the contents of *Short Practice of Surgery* and should be of value to those students using this textbook. The questions, some of which are validated by computer analysis, are either of the single-response variety or the determinate-response kind. The vast majority of questions included in the book relate to f al knowledge on the subject and few, if any, of th tions have problem-orientated stems that test the a to manage a specific clinical situation.

Apart from this omission, the questions are well thought out and clearly expressed and cover the essentials of the subject.

BRENDAN DEV

The Acute Abdomen for the Man on th et

J. C. Angell. Third edition. 215×1 n. Pp. 116. 1978. Tunbridge Wells: Pitman Medical. £1

THIS is just the book for the inexperienced house surgeon or junior registrar. It is short and written in an easy, colloquial manner; it could easily be read between being appointed and taking the post. It is full of sound advive about the acute abdomen. The great asset of the book is the fact that it is an account of the author's own experience and what he has observed. He does not hesitate to give an account of his own mistakes and what he has learnt from them. All would-be surgeons should read this book. It will be of great practical value.

Management of Primary Bone and Soft Tissue Tumors

Proceedings of the Annual Clinical Conference on Cancer at the University of Texas, M. D. Anderson Hospital and Tumor Institute. 230×150 mm. Pp. 474. Illustrated. 1977. London: Year Book Medical Publishers. £31·00.

THE Year Book Medical Publishers produce eminently readable, organized tomes with beautifully reproduced histology and radiology. The proceedings of the Annual Clinical Conference from Houston in 1976 is no exception. The management of primary bone and soft tissue tumours is discussed by staff members of the M. D. Anderson Hospital and invited speakers. The first two contributions are by the Heath Memorial Award recipients; Dr Franz Enzinger giving his usual didactic and lucid exposition on benign lipomatous tumours simulating sarcomas, which has the authority we associate with this author, and Dr Wataru Sutow relating the changes in the treatment of rhabdomyosarcoma and osteosarcoma in children to chemotherapy policy. There is quiet insistence by several authors that the prognosis in bone and soft tissue sarcomas has definitely improved owing to the addition of aggressive chemotherapy schedules and that this will be reflected by long term sur al as well as in increased disease-free intervals. Other outstan g chapters include a review of the histological classification of bone tumours by Harlan J. Spjut and appraisals of the place of conservative or radical surgery in bone and soft tissue sarcomas.

Although it is easy to criticize the publication of proceedings on the grounds of patchily covering the subject and the fact that such up-to-date are already past history by the time they appear in p is book is a worth-while statement. The chapters are by acc ed experts in a fast-moving field and give an overall review, in many instances, of the state of play at present. I think it is a useful, albeit expensive, addition to any oncological, orthopaedic or pathological department library.

MICHAEL A. EDGAR

Atlas of Endoscopic Retrograde Cholangiopancreatography

Edited Edward T. Stewart, Jack A. Vennes and Joseph E. Greenen. 290×215 mm. Pp. 366+xvi, with 367 illustrations. 1977. St Louis: Mosby. £35·45.

THERE is ample justification for an atlas of this kind now that endoscopic retrograde cholangiopancreatography (ERCP) is so widely used in the investigation of pancreatic and biliary tract disorders. It is generally agreed by those with experience of ERCP that radiograph interpretation is far the most difficult aspect of the procedure. Biliary tree radiology is already familiar but pancreatograms are not and, contrary to the advice of the authors of this atlas, many endoscopists do not have the assistance of an interested radiologist.

This volume is both a manual of ERCP as well as an atlas of radiographs, and as such it includes lucid chapters on endoscopic and radiological technique. In the section on endoscopic technique there is surprisingly little emphasis on the use of the short route to the papilla, which is only mentioned as an alternative manoeuvre if initial attempts at cannulation are unsuccessful, although it gives better control and reduced irradiation of the fibre bundle. There is no reference to the use of hyoscine butylbromide (Buscopan) as a duodenal relaxant because it does not have FDA approval in the United States although it is widely used in this country. A section on the endoscopic appearances of the duodenal loop and papilla would not have been out of place, since the endoscopic examination forms an integral part of the whole procedure.

The atlas itself is well planned and executed with a full and comprehensive index. Descriptions of the embryological development and normal anatomy with variants of both pancreatic and biliary tree precede the chapters on pathological conditions. Clinical details, radiographs and their interpretation are restricted to one or two pages per case and are generally most informative. The examples selected come largely from the author's own collection and this is therefore a highly personal account of the subject.

Considering the cost of the book, however, too many of the radiographs are either hazy or the details in them are obscured by excess contrast material. The examples of the normal pancreatogram and biliary tree are good with many lateral views to show extra detail. Pseudocysts are covered to excess, even though the authors warn repeatedly against pseudocyst filling because of the risks of sepsis. The difficulty of distinguishing between pancreatic cancer and pancreatitis is not sufficiently emphasized in the introduction to these sections, although the authors freely admit their own confusion in the legends to the many examples given and they further stress the value of clinical information for correct interpretation of radiographs.

east Cancer—Advances in Research

Edited William L. McGuire. 227×15
Illustrated. 1978. Edinburgh: Churchill L

THIS, the first of a series of books to be e
McGuire, in which it is hoped to present
us aspects of breast cancer, is concern
s of treatment and includes reviews
chemotherapy, endocrine tre nent and
e selected authors are master of th r su
orities; although much information
sed them elsewhere, its gathering together
volume will save considerable time and effort for th
who wishes to keep abreast of modern developments. There is also a comprehensive account of the pathology of the disease and its relationship to its natural history, written by Dr Edwin Fisher.

Quite apart from the practising clinician, there is a considerable content of fundamental knowledge which will interest the clinical investigator. Dr McGuire's own chapter on endocrine therapy is a good example; it is a masterly account of the fundamental as well as the therapeutic principles involved. He is to be congratulated on his initiative in producing what should be a very useful series of books. If the standard of succeeding volumes is up to this first one, the series will be a valuable aid to those interested in this common disease.

A. P. M. FORREST

Aspiration Cytology of the Breast

Hubert Schöndorf (translated by Volker Schneider). 245×170 mm. Pp 141+vii. 1978. Eastbourne: Holt–Saunders. £18·25.

ASPIRATION cytology for the diagnosis of breast lumps is practised more frequently in Europe and in Scandinavia than in Britain. This small book, with clearly written and concise text, and beautifully reproduced illustrations, details the method and provides a reference atlas for the interpretation of smears. Not that the diagnosis of breast smears can be learnt from a book. As cell detail is often lost, one must rely on nuclear characteristics, considerable skill and experience.

The author recommends that a solid discrete lesion can safely be left in the breast provided mammography and needle aspiration cytology do not provide evidence of malignancy. In our hands, needle aspiration is used to differentiate cystic from solid lesions, to treat cysts and to provide a provisional diagnosis based on cytology of the nature of a solid lesion; but we adhere to standard British practice and would still recommend that all palpable solid lesions are surgically removed.

Another interesting difference from British tradition is the origin of this book in a department of gynaecology; in many centres in Germany, breast disease is treated by a gynaecologist rather than a general surgeon.

This small book is very expensive but it is of value to those who are interested in this diagnostic technique.

discussion to t urethra and ad ne mechanisms.
Great emp a is laid on the pla of ureth scopy using
carbon dioxide in making an accurate assessment of the problems, and there are many line drawings on the endoscopic appearances of the bladder neck.

I think most urologists involved in female urological problems, especially incontinence, take more note of videocystographic appearances of the bladder neck and urethra rather than endoscopic views. There is a good chapter on diseases of the urethra with a good account of urethral diverticulae, and bladder drainage is dealt with adequately. There is much useful information in the book, but certain topics are dealt with very inadequately, and I think the treatment of the vesicovaginal fistula could be elaborated. The importance of bladder instability in urinary incontinence is emphasized, and techniques of investigation and treatment discussed.

This book can be recommended to gynaecologists who are new to this field, but I doubt that urologists would find the depth of discussion adequate.

Carbamoyloxy side-chain:
protects antibiotic from being metabolised

▼Prescribing information

Indications
'Mefoxin' is a broad-spectrum bactericidal antibiotic indicated for the treatment of infections caused by susceptible strains of Gram-positive and Gram-negative pathogens both aerobic and anaerobic.

'Mefoxin' has been clinically effective not only in infections due to antibiotic-sensitive organisms, but also in infections due to organisms resistant to one or more of the following antibacterial agents: penicillin, ampicillin, carbenicillin, tetracyclines, erythromycin, chloramphenicol, cephalosporins, kanamycin, gentamicin, tobramycin, and sulphamethoxazole-trimethoprim.

Many Gram-negative pathogens are resistant to penicillins and cephalosporins through the action of the β-lactamases which are produced by these pathogens. 'Mefoxin' is remarkably stable in the presence of these bacterial β-lactamases, both penicillinases and cephalosporinases. Hence, the clinical efficacy of 'Mefoxin' extends to many infections caused by such pathogens.

'Mefoxin' is indicated for the treatment of the following infections caused by sensitive bacteria:
peritonitis and other intra-abdominal and intrapelvic infections; female genital tract infections; septicaemia; urinary tract infections; respiratory tract infections; bone and joint infections; and skin and soft-tissue infections.

'Mefoxin' is indicated for adjunctive therapy in the surgical treatment of infections, including abscesses, infection complicating hollow visceral perforations, cutaneous infections, and infections of serous surfaces, whether caused by aerobes, mixed aerobes and anaerobes, or anaerobes.

icrobiology
'Mefoxin' is active *in vitro* against:
erobic bacteria
ram-positive cocci including: Staphylococci: (including coagulase-positive, coagulase-negative, and penicillinase-producing strains); Group A beta-haemolytic streptococci *(Streptococcus yogenes);* Group B beta-haemolytic streptococci *(Streptococcus galactiae); Streptococcus pneumoniae (Diplococcus pneumoniae);* other streptococci (except group D streptococci including enterococci, most strains of which are resistant, e.g. *Streptococcus faecalis). Gram-negative cocci* including: *Neisseria gonorrhoeae* (including penicillinase-producing strains); *Neisseria meningitidis. Gram-negative rods (facultative anaerobes)* including: *Escherichia coli; Klebsiella pneumoniae;* Klebsiella spp.; *Proteus mirabilis.* *Proteus* (indole-positive): *Proteus vulgaris; Proteus rettgeri; Proteus morganii; Haemophilus influenzae; Serratia marcescens;* Providencia spp.; Salmonella and Shigella spp.

Anaerobic bacteria
Gram-positive cocci including: Peptococcus spp.; Peptostreptococcus spp.; Micro-aerophilic streptococcus. *Gram-positive rods including: Clostridium perfringens;* Clostridium spp.; Eubacterium spp.; *Propionibacterium acnes. Gram-negative cocci including:* Veillonella spp. *Gram-negative rods including: Bacteroides fragilis; Bacteroides melaninogenicus;* Bacteroides spp. (including both penicillin-susceptible and penicillin-resistant strains); Fusobacterium spp.

'Mefoxin' is active against some strains of the following bacteria: *Acinetobacter calcoaceticus var. anitratum (Herellea vaginicola); Acinetobacter calcoaceticus var. lwoffi (Mima polymorpha); Alcaligenes faecalis;* Citrobacter spp. and Flavo-bacterium spp.; Enterobacter spp.

'Mefoxin' is not active against Pseudomonas, most strains of enterococci and many strains of *Enterobacter cloacae.*

Dosage and administration
'Mefoxin' may be administered intravenously or intramuscularly. (See reconstitution directions for each route below.) Dosage and route of administration should be determined by severity of infection, susceptibility of the causative organisms, and condition of the patient.

Therapy may be started while awaiting the results of susceptibility testing.

Dosage: The usual adult dosage is 1 g or 2 g of 'Mefoxin' every eight hours. (See chart.)

In adults with renal insufficiency, an initial loading dose of 1 g or 2 g may be given. After a loading dose, the following recommendations for *maintenance dosage* may be used as a guide.

Usual adult dosage

Type of infection	Dose	Frequency	Total daily dosage
Uncomplicated	1 g	Every 8 hours (occasionally every 6 hours)	3 g (4 g)
Moderately severe or severe	2 g	Every 8 hours (occasionally every 6 hours)	6 g (8 g)
Infections generally needing antibiotics in higher dosage	3 g (2 g)	Every 6 hours (Every 4 hours)	12 g

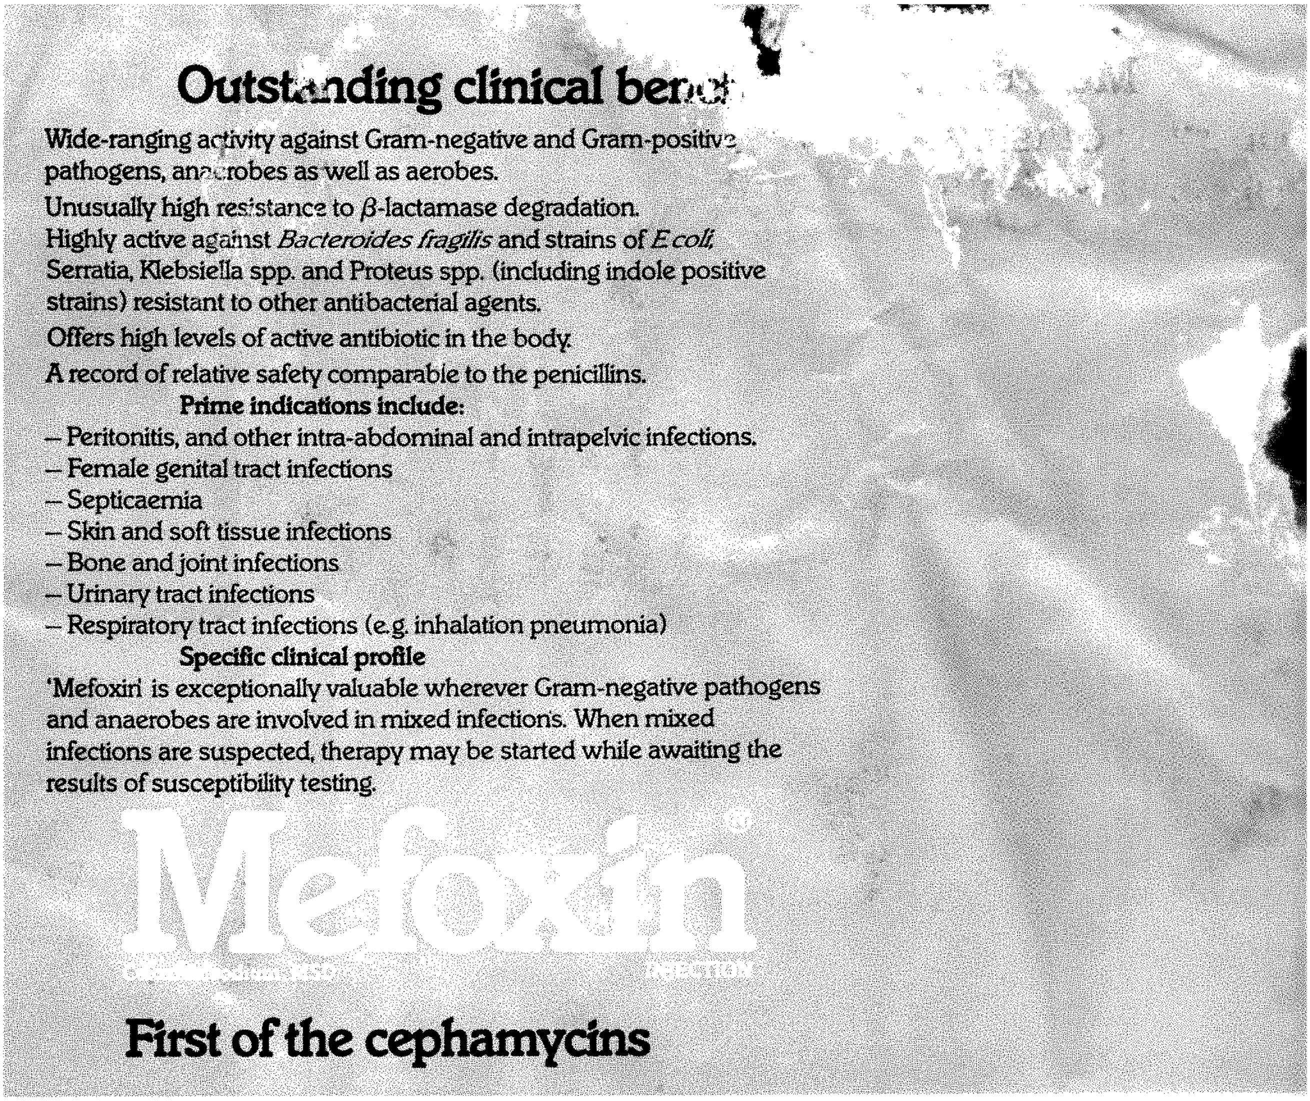
Maintenance dosage of 'Mefoxin' in adults with reduced renal function

Renal function	Creatinine clearance (ml min)	Dose	Frequency
Mild impairment	50-30	1-2 g	Every 8-12 hours
Moderate impairment	29-10	1-2 g	Every 12-24 hours
Severe impairment	9-5	0.5-1 g	Every 12-24 hours
Essentially no function	<5	0.5-1 g	Every 24-48 hours

In the patients undergoing haemodialysis, the loading dose of 1 to 2 g should be given after each haemodialysis, and the maintenance dose should be given as indicated in the table above.

Intravenous administration: reconstitute 'Mefoxin' with Water for Injection BP: 1 g is soluble in 2 ml. Although 'Mefoxin' is very soluble, for intravenous use it is preferable to add 10 ml of Water for Injection BP to the 1 g vial or the 2 g vial. Shake to dissolve and then withdraw entire contents of vial into syringe.

For direct intravenous injection, 'Mefoxin' may be slowly injected into



Outstanding clinical benefit

Wide-ranging activity against Gram-negative and Gram-positive pathogens, anaerobes as well as aerobes.

Unusually high resistance to β-lactamase degradation.

Highly active against *Bacteroides fragilis* and strains of *E.coli*, Serratia, Klebsiella spp. and Proteus spp. (including indole positive strains) resistant to other antibacterial agents.

Offers high levels of active antibiotic in the body.

A record of relative safety comparable to the penicillins.

Prime indications include:

– Peritonitis, and other intra-abdominal and intrapelvic infections.
– Female genital tract infections
– Septicaemia
– Skin and soft tissue infections
– Bone and joint infections
– Urinary tract infections
– Respiratory tract infections (e.g. inhalation pneumonia)

Specific clinical profile

'Mefoxin' is exceptionally valuable wherever Gram-negative pathogens and anaerobes are involved in mixed infections. When mixed infections are suspected, therapy may be started while awaiting the results of susceptibility testing.

Mefoxin®
[illegible] sodium, MSD INJECTION

First of the cephamycins

the vein over a period of 3 to 5 minutes or may be given through the tubing when the patient is receiving parenteral solutions.

An intermittent intravenous infusion of 'Mefoxin' may be employed when large amounts of fluid are to be given. However, during infusion of the solution containing 'Mefoxin', it may be advisable temporarily to discontinue administration of any other infusion solution at the same site (by using an appropriate IV infusion set).

A solution of 'Mefoxin' may also be given by continuous intravenous infusion (see below for compatibility and stability).

Intramuscular administration ONLY
Reconstitute 'Mefoxin' 1 g with 2 ml of Water for Injection BP, or 0.5% or 1% lignocaine hydrochloride (without adrenaline) solution. 'Mefoxin' is given by deep injection into a large muscle mass. Avoid injection into a blood vessel.

Compatibility and stability
A solution of 'Mefoxin' in Water for Injection BP may be added to the following solutions. 0.9% Sodium Chloride Injection BP, 5% or 10% Dextrose Injection BP, Dextrose and Sodium Chloride Injection (5%/0.9%, 5%/0.45%, or 4.3%/0.18%), Lactated Ringer's Injection USP, 5% Dextrose in Lactated Ringer's Injection, 5% or 10% invert sugar in water, 10% invert sugar in saline solution, 4.2% Sodium Bicarbonate Injection BP, M/6 Sodium Lactate Injection BP.

'Mefoxin', as constituted to 1 g/10 ml with Water for Injection BP, Water for Injection BP preserved with parabens or benzyl alcohol, 0.9% Sodium Chloride Injection BP, or 5% Dextrose Injection BP, maintains satisfactory potency for 24 hours at room temperature, for 96 hours under refrigeration, and for 13 weeks in the frozen state.

'Mefoxin' can be administered concomitantly with such antibiotics as gentamicin, tobramycin, carbenicillin or amikacin. When 'Mefoxin' is administered with another antibiotic, they should not be mixed in the same syringe.

Contra-indications
'Mefoxin' is contra-indicated in persons who have shown hypersensitivity to cefoxitin. In the absence of clinical experience, 'Mefoxin' should not be administered to patients who have shown hypersensitivity to cephalosporins.

Precautions
There is some clinical and laboratory evidence of partial cross-allergenicity between cephamycins and other β-lactam antibiotics, penicillins, and cephalosporins. Severe reactions (including anaphylaxis) have been reported with most β-lactam antibiotics.

Before therapy with 'Mefoxin', careful inquiry should be made concerning previous hypersensitivity reactions to β-lactam antibiotics. 'Mefoxin' should be given cautiously to penicillin-allergic patients.

Any patient who has demonstrated some form of allergy particularly to drugs, should receive antibiotics cautiously. If an allergic reaction to 'Mefoxin' occurs, the drug should be discontinued.

The total daily dosage should be reduced when 'Mefoxin' is administered to patients with transient or persistent reduction of urinary output due to renal insufficiency (see 'Dosage and administration') because high and prolonged serum antibiotic concentrations can occur from usual doses.

Interference with laboratory tests
A false-positive reaction to glucose in the urine may occur with reducing substances but not with the use of specific glucose oxidase methods.

Use in pregnancy
Use of the drug in women of childbearing potential requires that the anticipated benefits be weighed against possible hazards. Reproductive and teratogenic studies have been performed in mice and rats and have revealed no evidence of impaired fertility or harm to the foetus due to 'Mefoxin'. There are no controlled studies with 'Mefoxin' in pregnant women.

Nursing mothers
'Mefoxin' is excreted in human milk.

Infants and children
Pending the outcome of clinical trials in progress, the conditions for use of 'Mefoxin' in infants and children remain to be defined.

Side effects
'Mefoxin' is generally well tolerated. Side effects rarely require stopping treatment and usually have been [illegible].

Local reactions
Thrombophlebitis has occurred with [illegible]. Pain induration and tenderness after [illegible] have been reported.

Allergic
Maculopapular rash urticaria pruritus [illegible] other allergic reactions have been noted rarely.

Gastro-intestinal
Diarrhoea has been reported rarely.

Blood
Transient leucopenia and neutropenia [illegible]. Some individuals particularly those with azotaemia [illegible] positive direct Coombs tests during therapy with [illegible].

Liver function
Transient elevations in SGOT SGPT [illegible] alkaline phosphatase have been reported rarely.

Kidney
Elevations in serum creatinine and or [illegible] have been observed. The role of 'Mefoxin' in changes in renal function tests is difficult to assess since factors predisposing to [illegible] azotaemia or to impaired renal function usually have been present.

Presentation
In vials containing 1 g or 2 g of cefoxitin as the sodium salt. Each gram of cefoxitin contains approximately [illegible] sodium.

Product licence numbers: 1 g 0025/0134 2 g [illegible]

Product authorisation numbers: 1 g PA 35/40/1 [illegible] 35/40/2

Issued October 1978

Additional information is available to the medical profession on request.

Basic NHS cost is £4.47 for the 1 g vial, and [illegible] for the 2 g vial.

A comparison between disposable and no[illegible]ispo suction drainage units: a report of a contr[illegible] tri

B. J. BRITTON, O. J. A. GILMORE, J. S. P. LUMLEY AND W. M. CAS[illegible]

SUMMARY

A randomized trial of high vacuum Redivac drains and low vacuum Portovac drains has been conducted in 46 female patients undergoing simple mastectomy through a transverse skin incision. The Redivac units drained less fluid, stayed in place for a day less than the Portovac units and were emptied once less often.

DRAINAGE of surgical wounds is a long established surgical practice. It has, however, been subjected to relatively few clinical trials. Furthermore, a prospective study of over 20 000 wounds demonstrated that open drains increase the overall infection rate and require a great deal of nursing time, although they do reduce the incidence of intra-abdominal sepsis (Cruse and Foord, 1973). The introduction of suction drainage (Murphey, 1947) and, later, the evacuated glass bottle (Redon, 1955) offered new opportunities, and there is now evidence that this closed vacuum system has significant advantages in mastectomy wounds (Morris, 1973; Bourke et al., 1976). The desire for single-use disposable appliances has led to the introduction of plastic low vacuum drainage units, but these have several theoretically undesirable features (Lumley et al., 1974). We have therefore conducted a randomized clinical trial to compare the high vacuum Redivac system against the low vacuum Portovac drainage unit in surgical patients.

Patients and methods

Only female patients undergoing simple mastectomy without axillary clearance were eligible for the trial. Patients were randomly allocated at the end of the operation according to instructions revealed in a numbered enevelope labelled R for Redivac (Zimmer Orthopaedic Ltd) or P for Portovac (Howmedica UK Ltd). The operations were all performed in a similar manner by four surgeons using transverse skin incisions. Subcutaneous sutures were not used and the skin was closed with interrupted 3/0 black silk mattress stitches. Two perforated tubes were used, one placed along the base of the lower skin flap, the other in the axilla. Both tubes were connected to one suction bottle. The wound was dressed with a sterile adhesive dressing without pressure. Several variables of potential importance such as the length of the skin incision, the presence of tension in the flaps and the cup size of the patient's brassière were also recorded.

After the operation no restrictions were placed on movement of the arm and the drains were emptied or changed as follows. Both systems were only touched either when they were full or when the vacuum had expired. In the case of the Redivac a completely new sterile evacuated bottle was then connected whilst in the case of the Portovac, fluid was drained out, the bellows compressed and the drain plug replaced. Each time a drain was changed or emptied the contained fluid was measured and sent for culture. All drains were removed when the drainage volume in a 24-h period was less than 25 ml. At this time the tips of the perforated tubes, a swab of the drain site and the contents of the containers were all sent for culture.

Wounds were inspected for infection, necrosis, breakdown and fluid under the flaps on the fifth, seventh and ninth postoperative days. Any wound discharge was swabbed and cultured and wounds were classified as either clean or infected. Infection was diagnosed if (*a*) at any time a purulent discharge occurred or (*b*) a profuse growth of an organism was obtained from the swab of a serous discharge. Necrosis or breakdown occurred if a length of wound greater than 1 cm necrosed or separated. Other objective criteria of wound healing such as the time of suture removal and the day of discharge from hospital were noted as well as the presence or aspiration of fluid from beneath the skin flaps. Administration of antibiotics was avoided both before and after operation. Statistical comparisons between the two groups were made using either Student's t test or the χ^2 test for 2×2 tables.

Table I: COMPARISON OF THE PHYSICAL CHARACTERISTICS OF THE PORTOVAC AND REDIVAC GROUPS

	Portavac ($n = 24$)	Redivac ($n = 22$)	P

[illegible] rs of [illegible] tween [illegible] all breas [illegible] tainer drain [illegible] as 145 ml in [illegible] the Redivac group. [illegible] drains [illegible] o emptied at least once [illegible] and [illegible] in place longer, on average by about a day (*Table II*). There was no significant difference in the number of positive cultures from fluid, bottles or drain tips. Clinically 6 wounds became infected in the Portovac group and 2 in the Redivac group. Necrosis and breakdown occurred in 6 and 5 patients respectively whilst 1 patient in each group required aspiration. Of the 6 clinically infected wounds in the Portovac group, 4 were associated with necrosis and breakdown of the wound. In addition, 2 wounds became infected without necrosis and 2 wounds necrosed without infection. In the Redivac group 2 wounds developed infection without necrosis and 5 wounds necrosed without infection.

Patients in the Portovac group stayed in hospital about 2 days longer than those in the Redivac group but this was not statistically significant (*Table II*).

Discussion

In our laboratory study (Lumley et al., 1974) we assumed that the disposable type drains with a lower vacuum would require more frequent emptying. We demonstrated that one consequence of this was an increased liability to infection within the system which could then spread retrogradely on re-evacuation. Clinically we have shown that the Portovac drain did require more frequent emptying, drained a greater volume of fluid and needed to remain in place longer. However, this did not result in a greater incidence of positive cultures from either the bottle contents or the drain tips. The incidence of clinical wound infection in the Portovac group was, however, greater than in the Redivac group but 4 of the 6 infections were associated with necrosis of the skin edges. Overall 14 of the 46 patients in this series developed either infection or necrosis of the wound. Mastectomy, with its large skin flaps, is usually associated with a high incidence of wound problems, which may occur in up to 2 out of every 5 patients following a radical mastectomy (Zintel and Nay, 1964). Although the Redivac drain has been associated with necrosis of skin (McCallum, 1961), this was probably in cases where very thin skin flaps were used and, in general, [illegible] n necrosis is more likely to be related to surgical chnique and the thickness and tension of the skin aps (Heald, 1973) rather than to the type of drain. he slightly greater average age of the patients in the ortovac group might also have contributed to the ncidence of skin necrosis, but this is unlikely to have [illegible] a major effect. Whilst the unbreakable nature of disposable drains is an advantage, the fact that [illegible] be completely emptied of fluid is a nuisance [illegible] ore, the Portovac drain is occasionally [illegible] vacuate and close singlehanded. In [illegible] patients with Portovac drains extra [illegible] be inserted into the closed incision [illegible] through the wound into the system. [illegible] f the Redivac drain therefore appear [illegible] its greater vacuum, which rapidly eliminates any dead space and approximates the skin flaps together and to the chest wall, thereby encouraging healing, reducing drainage and thus hospital inpatient stay.

Acknowledgements

We are extremely grateful to Mr L. P. Thomas, Mr D. E. Sturdy, Mr R. A. Payne and Professor G. W. Taylor for allowing us to study patients admitted under their care. We are grateful to Howmedica (UK) Ltd for supplying the Portovac drains.

Hypertrophic scarring [illegible] De[illegible] [illegible]s [illegible]u[illegible] randomized trial

J. E. P. SIMPSON, M. ORNSTEI[illegible] C. [illegible] ND A [illegible]

SUMMARY

In a randomized prospective trial of thr[illegible] skin suture an increased inciden[illegible] o[illegible] scarring in paramedian and ingui[illegible] w[illegible] found to be associated with the use [illegible]f 2[illegible] subcuticularly. However, the variance the type of suture was less than that as sex of the patient. The patient's opin[illegible] ance of the scar was the same [illegible]or methods used in skin closure.

DEXON is a synthetic, absorbable suture made by the polymerization of glycolic acid (PGA). The tensile strength, knotting properties and handling characteristics (Hermann et al., 1970; Katz and Turner, 1971) have been found to be satisfactory and surgeons from several specialties have used the material successfully in clinical practice (Dardik et al., 1971; Alveryd and Jacobson, 1975). In 1975, Clough and Alexander-Williams reported the use of Dexon subcuticularly in wound closure at a time when we found, from a retrospective review, an increased incidence of hypertrophic scar formation (Cox and Simpson, 1975). We now report a randomized prospective trial on the incidence of hypertrophy in abdominal wound healing and on whether the type or position of the suture material is important in the production of scarring. Fourteen other possible aetiological factors have been studied and a symptomatic inquiry made.

Patients and methods

Three methods of skin closure have been compared in inguinal and paramedian wounds: subcuticular 2/0 PGA suture, subcuticular 0 nylon suture and transverse interrupted 0 nylon sutures. A consecutive series of 152 patients undergoing surgery for inguinal hernia, gallstone disease or benign peptic ulceration gave informed consent to be randomly allocated to one of the three skin closure groups with or without a plastic spray dressing. Patients admitted to the trial were grouped by sex, age (under and over 50) and site of incision before randomization. The deep layers of all wounds were closed identically with continuous chromic catgut to the peritoneum or external oblique aponeurosis and continuous monofilament nylon to the rectus sheath.

A form was completed for each patient, recording the length and depth of the wound, the site and nature of any discharge, the surgeon, the duration of operation and the date of suture removal. Height, weight, girth and haemoglobin and plasma protein concentrations were also recorded. A note was made of the patient's reaction to the wound and of any particular symptoms such as itching. Measurements of the wound were made at 3 weeks, 3, 6 and 12 months after surgery. The width of the scar was measured with a calliper and an attempt then made to compress the tissue between the points placed on the edges of the scars. Scars were said to be hypertrophied when they were raised above the surrounding skin, and incompressible when the points of the calliper could not be brought together.

The data were analysed by a standard method described by Armitage (1971). The results were expressed as parameters for the main factors influencing the proportion of hypertrophied wounds. Each parameter represents the change in the natural logarithm of the odds on hypertrophy being caused by the corresponding factor. One level of each factor was absorbed into the general mean and did not appear in the analysis.

[illegible] ts (67 per cent) [illegible] moved away from the [illegible] and the hospital. One [illegible] carcinoma, 4 [illegible] se at the time of surgery [illegible] dehiscence. Characteristics of the [illegible] of the three groups are recorded in *Table I* and show that the groups are comparable.

Fifty-four patients (41 per cent) had hypertrophic scar formation, which was often segmental. The hypertrophy affected over two-thirds of the wounds 18 patients and less than one-third in 10. The worst example of hypertrophy was in a paramedian wound which was a 10-mm wide, half cylinder of incompressible purplish-pink tissue; more commonly hypertrophic segments were 3 or 4 mm wide, compressible by 1 or 2 mm and pink in colour. Hypertrophy was only rarely seen at the 3-week inspection but was usually apparent by 3 months if it was going to occur. Once formed, it changed little throughout the year of observation, except in 5 patients in whom it began to soften.

Use of spray as a wound dressing did not affect the incidence of hypertrophy, nor did the hypertrophy become aggressive, as in keloid scar formation. Twenty-three of the 48 wounds (47 per cent) closed with subcuticular PGA suture showed hypertrophy (*Table II*), an incidence significantly in excess of that seen with subcuticular nylon (37 per cent) ($P \sim 0{\cdot}04$ in a one-tailed t test). This hypertrophy was not dependent on the position of the suture material, since the incidence of hypertrophy was similar for nylon used subcuticularly (37 per cent) and as an interrupted suture (35 per cent). Therefore, the results for the two types of nylon suture were combined in the parametric analysis so that the standard errors were as follows: general mean, $0{\cdot}437 \pm 0{\cdot}392$; sex (male) $-1{\cdot}888 \pm 0{\cdot}583$; suture (PGA), $0{\cdot}795 \pm 0{\cdot}463$; incision (inguinal) $-0{\cdot}968 \pm 0{\cdot}632$; age (50) $0{\cdot}623 \pm 0{\cdot}440$.

The effect of sex is highly significant ($P < 0{\cdot}001$), the incidence of hypertrophy in females (72 per cent) far exceeding that in males (18 per cent) whichever form of wound closure was used. Even when paramedian wounds alone are considered the male incidence rises to 29 per cent (*Table III*). Patients under 50 (50 per cent) were more often affected than those who were older (34 per cent) but this did not reach significance at the 5 per cent level. Nor did the apparently large difference in incidence between the paramedian (60 per cent) and inguinal (14 per cent) wounds reach statistical significance when the other factors were taken into account. The residual χ^2 (deviance) was 5·429 with seven degrees of freedom, indicating that the model gives a good fit to the data.

No association was found between the presence of hypertrophy and the individual surgeon, the time taken to perform the operation, the use of a spray dressing, the presence of discharge from the wound or such patient characteristics as girth, haemoglobin and plasma protein concentrations. Too few patients came from abroad for the effect of race to be studied.

Thirty-nine patients (30 per cent) told us of itching in the wound which on 29 occasions (54 per cent) was associated with hypertrophy; it was less troublesome when clothes made of nylon were avoided. A hypertrophic wound was particularly uncomfortable if it crossed the waistband or was subject to pressure or rubbing in other ways, but it was not painful of itself. Of those patients with hypertrophic scars, 14 were disappointed (32 per cent) and 1 was disgusted by the appearance; 6 (7 per cent) were disappointed even when there was no hypertrophy. There was no difference between the three suture groups in the degree of satisfaction with the appearance.

Discussion

The cosmetic quality of abdominal scars is less important to the general surgeon than dehiscence and herniation and, in a busy surgical outpatients department, the patient's opinion of the scar is rarely sought. We have found that after straightforward abdominal surgery one-third of the wounds will show some degree of hypertrophy irrespective of the suture used. This is in keeping with the recently published results of Arabi and Alexander-Williams (1978), but using a stratified randomization and a statistical analysis designed for such a multi-factorial situation, this risk is significantly increased if PGA is inserted subcuticularly to close the skin. However, we do agree with Jones and Shorey (1975) that PGA suture has advantages since 14 per cent of our patients said they were apprehensive of suture removal, and avoiding suture removal saves nursing time.

Although patients complained of the appearance of a hypertrophic scar and of itching, they found less pain than had been previously described (Crockett, 1964). Less expected was the excessive frequency of hypertrophic healing amongst women, for some studies have reported equality between the sexes (Ketchum et al., 1974). At a 5 per cent level of significance, this study failed to confirm either the expected increased incidence of hypertrophy amongst younger patients (Ketchum et al., 1974) or the effect of the location and direction of the skin incision (King and Salzman, 1970), although there were trends in the expected direction.

Necrotizing sialometaplasia of palate

RANES C. CHAKRAVORTY, TATSUO YONEYAMA AND

SUMMARY

A patient with necrotizing sialometaplasia of the hard palate was treated with wide resection on a biopsy diagnosis of carcinoma. The literature on this recently identified entity is reviewed and the characteristic clinical features, histopathology and ultrastructure are summarized. To the best of our knowledge, no ultrastructural study concerning this entity has been previously reported. Unless recognized early, an extensive resection might be done needlessly.

IN a paper published in 1973, Abrams et al. reported on 7 patients (seen over an 8-year period) with ulcerating lesions of the palate that were generally diagnosed as being cancer but were not. These authors did not find any previous reports of this entity and termed it 'necrotizing sialometaplasia'.

Case report

E. C., a 54-year-old black male, was seen in the surgical clinic for a slightly tender lesion on the left side of the hard palate. About 3 weeks earlier he had been examined by a physician for some palatopharyngeal discomfort but no specific anomaly was noted in the oral cavity or pharynx. The patient had since developed a progressive swelling in the left hard palate which was tender but not painful and which had ulcerated 3 days previously. The patient was a heavy smoker, an occasional user of alcohol and had no other significant medical history.

Intraoral examination showed an ulcerated area about 1·5 cm in diameter on the right side of the hard palate. The base was occupied by shaggy yellowish necrotic tissue and the margins were sharply demarcated, with a red halo about 0·5 cm wide (*Fig.* 1). The lesion was mildly tender. The rest of the oral cavity, larynx and pharynx were unremarkable. Neck nodes were not palpable. Routine physical and laboratory examination were within normal limits. The VDRL test was negative. Radiographs of the area showed mild b palatal process of the left maxilla.

A biopsy of the lesion was initially read as an ulcer and fresh tissue was requested. The second biopsy was interpreted as squamous cell carcinoma. Two days later, the ulcerated area was widely excised with frozen section control until the margins were through normal tissue. The bone of the palate was left intact.

Postoperative healing was satisfactory though slower than expected. The final report on the excised specimen under light microscopy was necrotizing sialometaplasia. The patient remains free of any local recurrence at 18 months.

Microscopic examination

The surgical specimen was a 1·5-cm round ulcer with a smooth margin and large area of ischaemic necrosis involving mucosa,

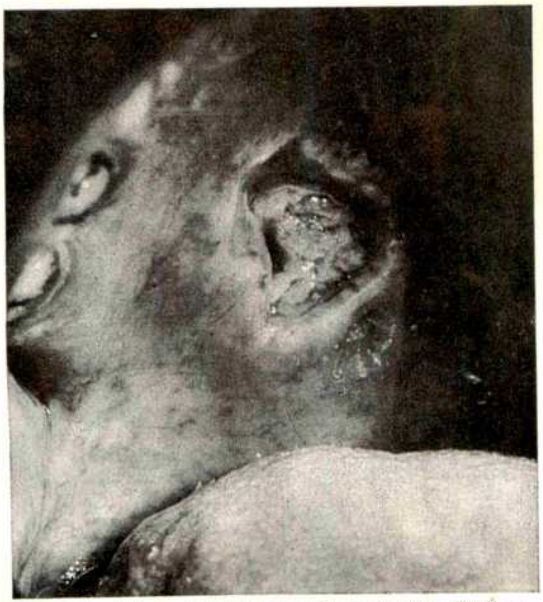

Fig. 1. The lesion, with sharp margins and a sloughy base.

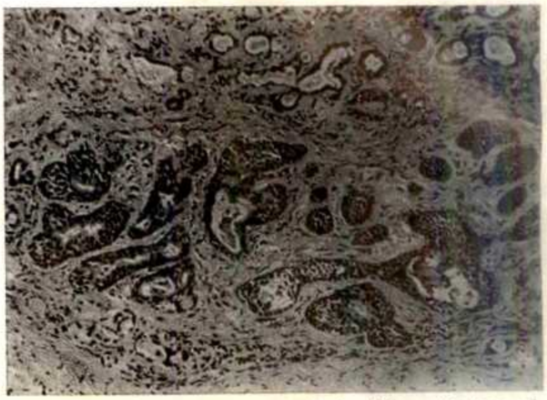

Fig. 2. Extensive squamous metaplasia of the epithelium of acini and ducts with infiltration of chronic inflammatory cells in the fibrous stoma. (HE. × 82.)

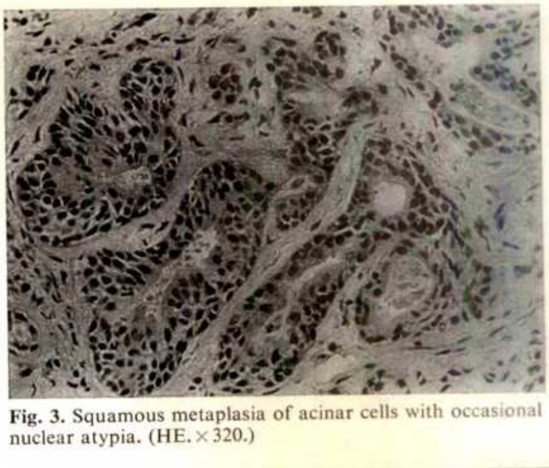

Fig. 3. Squamous metaplasia of acinar cells with occasional nuclear atypia. (HE. × 320.)

iopsy material from the lesion disclose
anges. The combination of pseudoepitheliomatou
plasia and nests of metaplastic squamous cells along with mucosal ulceration produced a picture mimicking well-differentiated infiltrating squamous cell carcinoma.

lectron microscopy

A gradual transition from relatively undisturbed acinar cells to metaplastic squamous epithelium was seen. The latter was evidenced by increased desmosomes, tonofibrils and retention of their secretory granules. Other intracytoplasmic organelles were not remarkable. The lateral borders of the canaliculi were also changing from loosely arranged microvilli, in the undisturbed cells, to a tight and relatively smooth border in the metaplastic cells. Occasional degenerating acinar cells revealed a single or coalescent degenerative vacuole, compressing the nucleus. Degenerative vacuoles were much less electron-dense than developing immature secretory granules and they were usually membrane-bound. Other structures, such as myoepithelial cells, basement membrane and blood vessels, were not emarkable. We did not observe any particulate matter uggesting a micro-organism as the possible aetiology of this disease.

Review of the literature

Since its initial description, about 30 patients afflicted with this disease have been reported in the literature. Males have predominated, with ages ranging between 18 (Pindborg and Harder, 1977) and 83 (Johnson, 1977). Clinical details are surprisingly vague and non-specific.

When documented, lesions have on occasion been painful. In most patients there had been at least a 3-week delay before medical attention was sought, testifying to the relative painlessness of the lesions. The use of tobacco has not always been documented though at least 2 patients had never smoked and some were teetotallers (Myers et al., 1975; Fechner, 1977). Our patient had a non-reactive VDRL test though one reported patient was known to have syphilis (Bannayan et al., 1976). The lesion was generally clearly to one or the other side of the midline though in a few instances bilateral lesions have been seen. At least 3 patients had a raised mass only without any ulceration. Significant cervical lymphadenopathy has not been recorded. Lesions biopsied were generally diagnosed as cancer (as was ours) and were thus treated by wide local excision except when the lesion spontaneously regressed because of patient delay. The benign and self-limiting nature of the lesion is evidenced by an 8-year follow-up of a patient who ven though the margins at sease.

aplasia of the palate is a self-
condition occurring in adults. No
ogical agents have been reported; we
er the electron microscope for microbial
ing this disease but the results were
ve. The fact that the disease occurs mainly in
inor salivary glands leads to onsider some form
of immunological e minor salivary
glands c gA than the parotid
here is no clinical or
rt this hypothesis, how-
s being the necrotizing or
nic stomatitis (Philipsen et al.,
ined as it has been described
in non smokers. Moreover, identical changes have been described in the major salivary glands (Bhargava and Monga, 1975; Batsakis, 1976) and in the mucous glands of the nasal cavity (Maisel et al., 1976; Johnston, 1977). Probably the lesions represent compromised local blood supply with reactive squamous metaplasia.

The lesion starts as a nodule on one side (it may be bilateral) and is generally painless, or nearly so, for a period of 2–3 weeks. It can ulcerate, producing either a flat or a raised ulcer with sharp margins, a necrotic yellow slough on the base and in some cases a reddish halo. The ulcer is generally painful and tender, and when left undisturbed (or following a simple biopsy) slowly but spontaneously heals in 6–8 weeks. No recurrence has been noted in any of the reported cases and in one patient who had incomplete excision (with disease in the excised margin) no recurrence was seen at 8 years (Abrams et al., 1973).

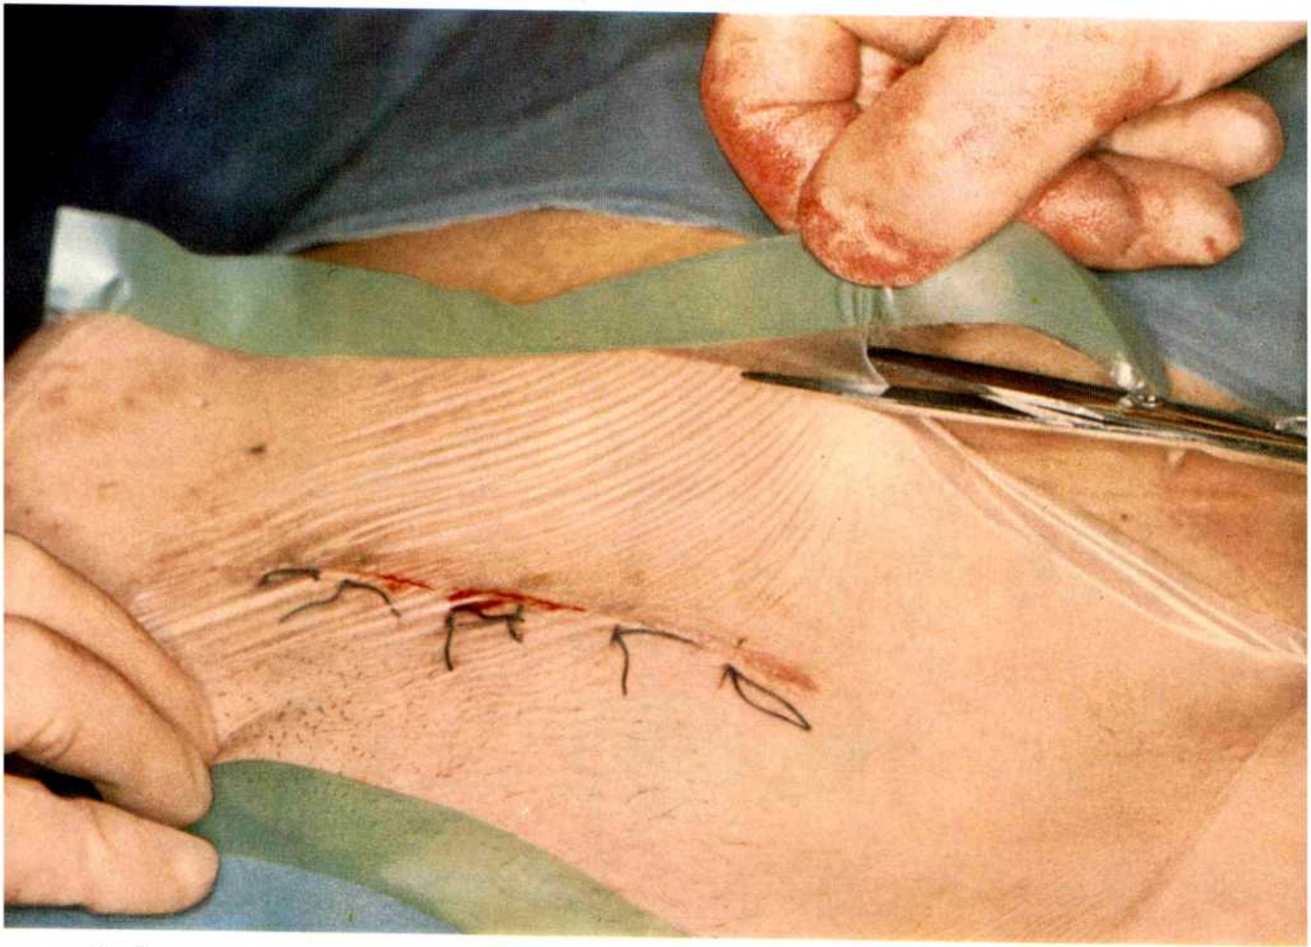
ISTOL

Op-Site.
The latest visual aid for surgeons in post-operative care.



Op-Site represents a significant advance in post-operative care. The transparent film allows constant wound observation without the need for removal, reducing the frequency of dressing changes. Not only does this save time and minimise patient discomfort, but it also reduces the risk of secondary infection–obvious benefits to the surgeon, nurse and patient.

In addition, by maintaining the wound in a moist state, Op-Site provides an optimum wound healing condition.*

Op-Site gives strong, conformable, protection and can be applied quickly and easily. Since it is waterproof, the patient can bathe without fear of wound contamination.

Op-Site is a Smith & Nephew product. Samples and a fully-illustrated leaflet are available on request.

Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, Broadmead House, 21 Panton Street, London SW1.* Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the Journal unless rights are reserved before publication. Original illustrations must be securely packed and protected.

Business communications should be sent to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery. Advertisements:* All communications should be addressed to *Hexagon Publishing Co. Ltd., 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone 0727 60641: telex 21827).

Manuscripts
Two good quality plain paper photocopies of all written and tabular material should be submitted and the original retained by the author. Illustrations should also be submitted in duplicate clearly marked on the back to show number, orientation and author. Legends should be typed on a separate sheet. For halftones, unmounted glossy photographs or positive prints (not X-ray negatives or slides) are required. Colour prints should be accompanied by the original transparencies; a contribution to the cost of reproduction is always necessary. Drawings must be ready for reproduction: a leaflet giving details of the preparation of artwork is available from the publishers and must be consulted. Tables are typed on separate sheets and must have a Roman identifying number plus a short descriptive heading.

Presentation of statistics
Authors are reminded that: (*a*) the methods section of a paper should contain a mention of any statistical technique used: if the method is new or unfamiliar either a reference should be given or a description included as a brief appendix; (*b*) if alternative techniques could have been applied to the data, a short justification of the method is often appropriate; (*c*) in clinical trials, the confidence or tolerance limits of the results should be quoted, particularly when formal statistical significance at the 5 per cent level is only just reached; (*d*) abbreviations for statistical terms should follow those used in *Documenta Geigy Scientific Tables*, 7th edition, 1970.

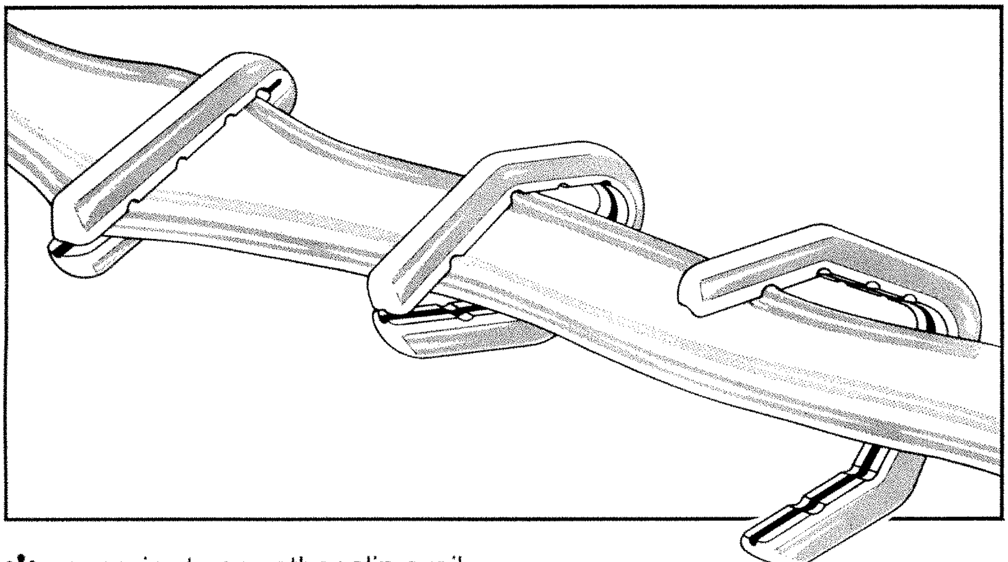
SI units
It is Journal policy to use SI units except for measurement of blood pressure where mmHg is preferred. Authors should consult: Baron D. N., Broughton P. M. G., Cohen M. et al. (1974). The use of SI units in reporting results obtained in hospital laboratories. *J. Clin. Pathol.* 27, 590–597. Reprints are available from British Medical Association, London.

References
The citation of references is by the Harvard system, a detailed description of which can be obtained from the Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE. Briefly the name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. More than two authors may be indicated in the text citation by 'et al.'. More than three authors may be indicated in the list of references by 'et al.'. The style of author and journal references should conform with the *Index Medicus:* sequence of referencing is author(s), year of publication, title of article, name of journal, volume number, first and last page numbers.

A reference to a book should give in order: the names and initials of all authors, editors or compilers, date of publication, title of book, edition number, place of publication, publisher's name, first and last page numbers of the contribution.

A more detailed list of instructions is published yearly in the January issue.

Weck® Hemoclips® Surgical occlusion proven in over 12 years' use



- ✱ superior to any other clip available will not slip off blood vessel; allows partial occlusion if necessary
- ✱ routinely used in more than 40 different surgical procedures
- ✱ pre-formed to direct pressure uniformly in the applier - true parallel closure without scissoring
- ✱ distal end closes first to encompass all the vessel
- ✱ available in four sizes

Hemoclip closure:
Left is the clip closed, providing a tenacious yet hypotraumatic grip.
Centre is the partially closed clip forming a ring. Right is the open clip; magnifying the longitudinal and transverse grooving - a milled, grooved surface that grips securely without slippage.

Now: together: a unique ostomy system and the best in skin care

SURGICARE System2

Trademark

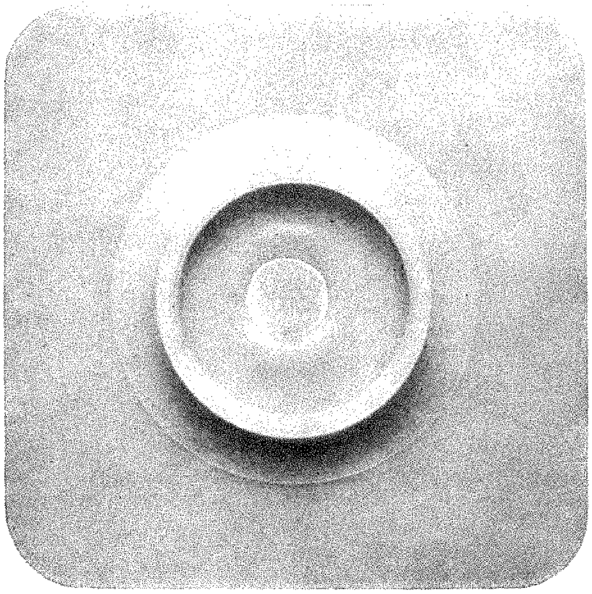
Surgicare™ System 2 saves the daily trauma of peeling off adhesive bags often resulting in irritation, soreness and discomfort. The Stomahesive™ with Flange can be left on the skin undisturbed for several days whilst pouches are replaced as often as necessary... so simply.

Kinder to the skin

Stomahesive™ with Flange may be used by patients who have experienced sensitivity reactions when using ordinary adhesives and karaya or where perspiration under the adhesive is a regular source of irritation and discomfort

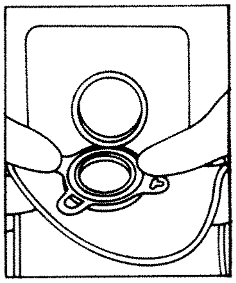
Unequalled comfort

The Stomahesive™ base will mould to irregular contours of the skin and is so easy to apply without wrinkling. Comfort is derived not only from the feel of Stomahesive™ against the skin but from the confidence that the appliance will be secure and leak free irrespective of the condition of the skin.



Avoids adhesive trauma

With the Stomahesive™ flange remaining undisturbed, pouches may be removed and replaced as necessary.



The colostomist, for example, may change pouches several times a day without the need to disturb the Stomahesive™ base and its flange.

Hollister conquers gas

At last - a highly effective flatus filter from Hollister

No leaks, no odour — Hollister have made sure that this new deodorising flatus filter is really effective and trouble-free.

Every colostomy patient knows the discomfort and embarrassment that occurs when a stoma bag swells up with flatus. Now Hollister have developed a flatus filter system that solves this problem successfully. Laboratory trials have proved its reliability.

Gas is released automatically through the unique Hollister* deodorising filter — packed with thousands of tiny odour-trapping granules of activated charcoal.

No leaky filter, no odour, no more discomfort or embarrassment. It really works. Hollister have conquered gas!

Why leading surgeons all over the world prefer SWANN-MORTON scalpels

Swann-Morton have devoted years of experience and research to produce the superb surgical blades that are the choice of the world's leading surgeons.

Swann-Morton products are made on high precision automatic machines designed by our own specialists. Scrupulous control is kept over all manufacturing stages to guarantee maximum uniformity, initial sharpness and durability.

All the nine universally accepted shapes are included in the Swann-Morton range of blades, and all of them are available in stainless or carbon steel.

The fine quality of Swann-Morton blades will continue to justify the preference of the world's surgical teams.

Noxyflex RESEARCH SPECTRUM

NOXYTHIOLIN I.N.N.

ANTIBACTERIAL
ANTIFUNGAL

ENDOTOXIN

TUMOUR CELLS

PERITONITIS

ADHESIONS

ANASTOMOSIS
HEALING

Active ingredients:
Noxythiolin I.N.N. (Noxyflex-S) or noxythiolin with amethocaine HCl B.P. (Noxyflex)

Indications:
1-2.5% solution for prophylaxis and management of infections topically and in accessible body cavities.

Contra-indications:
None reported.

Geistlich Chester

Full prescribing information and research data available on request.

PL 0184/5012 and /5013

Basic NHS price:
10 x 2.5g vials £34.60

Geistlich Sons Limited Newton Bank Long Lane Chester CH2 3QZ Telephone 0244 47534

Growing evidence...widening usefulness

ENDOMETRIOSIS

"...at least as effective as the best 'pseudo-pregnancy' treatment...no initial exacerbations of symptoms, rapid return of normal hormonal function and generally mild side-effects".[1]

BENIGN BREAST DISEASE

"...a significant decrease and elimination of breast pain and tenderness (and of) nodules and lumpy areas..."[2]

MENORRHAGIA

"The efficacy of danazol in the control of heavy menstrual blood loss could prove of value in clinical practice".[3]

GYNAECOMASTIA

"Danazol resulted in a regression of the gynaecomastia in the majority of the present patients studied..."[4]

1. J. int. med. Res. (1977) 5 (Suppl. 3): 86-91.

Danol

danazol

controls pituitary gonadotrophins without exerting oestrogenic or progestogenic activity

WINTHROP

For the treatment of endometriosis, infertility associated with endometriosis, fibrocystic mastitis, virginal breast hypertrophy, gynaecomastia, primary constitutional precocious puberty and other similar endocrine disorders where control of the release of pituitary gonadotrophins LH and FSH would be of therapeutic value.

Danol (danazol 200 mg). PL 0071/0095. Bottles of 100 capsules. Basic N.H.S. cost of one day's treatment £1.42 (3 capsules).

Danol-½ (danazol 100 mg). PL 0071/0094. Bottles of 100 capsules. Basic N.H.S. cost of one day's treatment 72 p. (3 capsules).

Dosage. Adults 200-800 mg daily, children 100-400 mg daily. See Data Sheet for details.

Contra-indications: Pregnancy.

Precautions. 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop.

Side Effects. Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control.

Danol is a trade mark. Further information available from:– Winthrop Laboratories Surbiton-upon-Thames Surrey KT6 4PH.

Immunity in malignant disease*

MICHAEL WOODRUFF†

WHAT is meant by *tumour immunology*? A possible definition of an immunological reaction is a response triggered by antigen and mediated by specific antibody or specifically sensitized lymphocytes. In the present context this is too restrictive and I propose to regard tumour immunology as embracing all those aspects of the host reaction that depend on recognized differences between tumour cells and normal cells. The discussion will therefore embrace aspects of tumour biology that a purist might prefer to call para-immunological.

Let us begin, however, not with immunology but with some dogmas concerning cancer which were current when I was a medical student, and have been a long time a-dying. Here they are: the cause of cancer is largely unknown; cancer is often of multifocal origin; lymph nodes provide an efficient, albeit temporary, barrier to the spread of cancer via lymphatics; dissemination of cancer via the bloodstream occurs only late in the life-history of a tumour; cancer is autonomous.

Aetiology of cancer

It is generally accepted that the primary event in the development of a tumour is a heritable change—either a mutation or series of mutations, or a so-called epigenetic change of the kind which underlies the process of differentiation during embryological development—in one or more cells, as a result of which the response of the cell and its descendants to factors that regulate the growth of normal cells is profoundly altered. How are such changes, genetic or epigenetic, brought about?

It is commonplace to describe human tumours as spontaneous, in contrast to tumours in experimental animals which are often induced with chemical carcinogens, or by radiation, viruses or other agents. This can, however, be dangerously misleading. If by spontaneous we mean that human tumours are not deliberately induced we may be open to criticism on semantic grounds but what we are saying is, in the main, true. If we mean that, for a given tumour, no aetiological agent has yet been identified, what we are saying may be true today but false tomorrow. If we mean that human tumours, as a general rule, develop independently of any external agency—*sua sponte*—we are in terms of meaning beyond reproach but what we are saying is false, for if one looks at the whole spectrum of human cancer it seems clear that, as with animal tumours, environmental and genetic factors may both be concerned in a cause.

I would like to discuss briefly the evidence in respect of chemical carcinogens, radiation and oncogenic viruses, because tumours induced with these agents in animals have important immunological properties which can be exploited therapeutically. Human tumours similarly caused might be reasonably expected to have similar properties.

It is over 200 years since Percival Pott suggested that the high incidence of carcinoma of the scrotum in chimney sweeps in England was due to prolonged contact with soot, though it was not until 140 years later that it was shown that skin cancer could be induced in experimental animals with coal tar. In 1930 Kennaway and Hieger succeeded in inducing cancer experimentally with a pure chemical substance, 1,2,5,6-dibenzanthracene, and since then well over a hundred compounds have been shown to be carcinogenic in experimental animals. It may be added, in parentheses, that with many of these so-called carcinogens it is their metabolic products rather than the parent substances which are carcinogenic, but this does not invalidate the argument.

When I was a student we had all, even in far-off Australia, heard of Pott's chimney sweeps, and of the aniline dye workers in Germany who frequently developed bladder cancer, but we thought of these as geographical curiosities that had little in common with the tumours we were likely to encounter. Today this view is no longer tenable in the light of the high correlation between the incidence of familiar tumours and exposure to substances known to be carcinogenic in animals, of which the best known example is, of course, the association between smoking and lung cancer. The conviction is growing that, as Sir Richard Doll and others have maintained, carcinogenic chemicals play a major role in the cause of human cancer.

Ionizing radiation is a powerful mutagen and can cause visible structural damage to chromosomes. It is also carcinogenic, as has been tragically demonstrated in many fields: the high incidence of various forms of cancer in the pioneers of radiology; in people employed in painting watch dials with luminous paint when this contained radium or mesothorium; in patients given Thorotrast for radiological visualization of the liver, or, more recently, X-ray therapy for ankylosing spondylitis; in children irradiated *in utero* in the course of radiological investigations on their mothers, or subsequently for haemangiomas or other conditions; and in patients exposed to radiation as the result of the atomic bombs dropped on Hiroshima and Nagasaki.

---

* Substance of the first SURGIKOS Lecture, Association of Surgeons, Sheffield, 6 April 1978.

† MRC Clinical and Population Cytogenetics Unit, Western General Hospital, Crewe Road, Edinburgh EH4 2XU.

Ultraviolet radiation, though non-ionizing, is also both mutagenic and carcinogenic and epidemiological studies have established a strong relationship between exposure to solar ultraviolet radiation and the incidence of cutaneous basal cell carcinoma, squamous cell carcinoma and malignant melanoma.

The role of viruses in human cancer is unclear. Direct evidence that a particular kind of human cancer is caused by a virus could only be obtained by totally unethical experimentation or as the result of an unfortunate accident in which people were injected with a vaccine which contained an active oncogenic virus. The case must therefore rest on circumstantial evidence. It would lead us too far afield to discuss this. Suffice it to say that there are strong grounds for believing that a DNA virus of the herpes group, the Epstein–Barr virus (*see* Epstein, 1970), plays an essential role in the cause of Burkitt's lymphomas and of squamous cell carcinoma of the nasopharynx as seen in Asia and parts of Africa; and some grounds for suspecting that the same virus may be concerned in carcinoma of the cervix. It also seems possible that an RNA virus, rather like the mouse mammary tumour virus, may play a part in breast cancer and other similar viruses may be implicated in osteogenic sarcoma and some forms of leukaemia.

Multifocal or monoclonal origin

As a medical student I had the great privilege of being introduced to the pathology of tumours by Dr Rupert Willis. He maintained, and other pathologists with a wide knowledge of human cancer and of precancerous lesions have continued to maintain, that many tumours are of multifocal origin. In recent years, however, it has become increasingly apparent that many tumours are to a large extent monoclonal, i.e. that the tumour cells are the descendants of a single somatic cell. The evidence for this is the discovery of a high degree of uniformity in respect of marker chromosomes and tumour-associated antigens; that plasma cell tumours, including human myelomas, produce one single immunoglobulin; and that heterogeneity which occurs in the normal tissues in women as the result of random inactivation of one X chromosome is often not found in tumours.

The last of these criteria has been widely used. The marker generally employed is the enzyme glucose-6-phosphate dehydrogenase (G-6-PD), which is the product of a gene carried on the X chromosome and exists in two forms, A and B, which can be easily distinguished by electrophoresis. Women who are heterozygous at the G-6-PD locus have two populations of normal cells, one producing the A form of the enzyme and the other the B form. However, if a tumour in such an individual is monoclonal, all the tumour cells should produce the same form of the enzyme, A or B, depending on which population the cell that gave rise to the tumour belonged to. This has proved to be the case with various neoplasms studied by Fialkow and others, including uterine fibroids, Burkitt's lymphoma, chronic myeloid leukaemia and carcinoma of the cervix, though not with others, including, for example, neurofibromas (Friedman and Fialkow, 1976). While some of the evidence is open to criticism on the grounds of the small numbers of tumours studied, it is, in general, highly convincing.

Can one reconcile a multifocal origin with evidence of monoclonality? It seems to me that one can, because a tumour which appears at a particular time to be monoclonal was not necessarily so *ab initio*; it may have become monoclonal because one particular clone of cells outgrew all others. Even when one clone predominates, the presence of a small number of foreign cells cannot be ruled out. As we shall see, many tumours contain dormant cells and there is no obvious reason why these should all belong to the dominant clone; indeed, the recent discovery by Pimm and Baldwin (1977) with experimental tumours, that cells from local recurrences following incomplete surgical excision differ antigenically from the original tumours, raises the possibility that dormant cells which are not members of the dominant clone may be responsible in some patients for local recurrence and perhaps also for the appearance of metastases, after surgical excision or radiotherapy.

When does dissemination occur?

Since 1863 when Virchow postulated that lymph nodes filter out particulate matter from lymph, it seems to have been widely accepted that they constitute an effective, albeit temporary, barrier to the passage of tumour cells. Experiments in animals have now shown two things. First, that radioactivity-labelled, but viable, tumour cells can pass through lymph nodes in a matter of minutes although dead cells may be trapped for a long time (Fisher and Fisher, 1966). Secondly, that the nodes draining tumour transplants, which rarely cause lymph node metastases, contain a number of tumour cells that are difficult to account for except on the basis that they are in process of traversing the node and will eventually reach the bloodstream (Hewitt and Blake, 1975).

Blood-borne dissemination has traditionally been regarded as a relatively late occurrence with many tumours. This belief provides the rationale for forms of treatment which are directed only to the local tumour and related lymph nodes. The demonstration at the time of operation of tumour cells in the bloodstream shows that dissemination may occur at least as early as this, and it is clear from the incidence of metastatic disease after adequate local excision of early primary tumours that tumour cells disseminated before or during operation quite often give rise to clinical metastases. That cells disseminated well in advance of operation can do this is clear from the work of Galasko (1975) and others on bone scanning in patients with breast cancer.

Attempts have been made to determine the time at which metastatic deposits in the lungs begin by observing the growth rate of each deposit from the time when it is first clearly recognizable in serial chest X-rays and extrapolating the growth curve back to the time when the estimated size of the metastasis was about that of a single cell. It is now clear that if a simple logarithmic growth curve is fitted the estimated time of origin may be far too early, but if a rather more complex method which allows for a decline in growth rate with increasing age (a Gompertz curve) is used, the estimate is likely to be much nearer to the truth. Such evidence as there is confirms that dissemination leading to metastasis can occur much earlier than we used to believe and quite often before patients present for treatment, even when there has been no undue clinical delay. It is this early dissemination which so often makes treatment in the form of surgical excision of a primary tumour, even with its possible lymph node metastases, insufficient and, if I may anticipate my later argument, I would add that our successes are probably often due not to our having removed *every* cancer cell, but to our having reduced the residual tumour burden to a level at which it can be dealt with by other mechanisms.

Autonomy

Not so long ago it was widely accepted that malignant tumours are, as Ewing (1940) expressed it, autonomous new growth of tissue. This dogma seems to have implied, first, that tumours are not influenced by any of the factors that control the growth and equilibrium of normal tissues, and, second, that no special homeostatic mechanisms, even of a rudimentary kind, exist for controlling carcinogenesis and tumour growth.

The falsity of the first of these dogmas became apparent when the fact that some tumours are hormone-dependent was firmly established by Huggins (1967). The case against the second may be considered under four headings: evolutionary considerations, clinical observations, studies of tumour cell population kinetics and immunological evidence.

It seems unlikely on evolutionary grounds that complex multicellular organisms could have developed as they have had they not evolved mechanisms to deal with what have been called asocial cells, i.e. cells which have survival advantages as cells but which are disadvantageous from the point of view of the organism as a whole. Cancer cells clearly fall in this category. The relevant clinical observations in this context are the occasional spontaneous regression of primary tumours, and of metastases after excision of a primary tumour, and the appearance and rapid growth of metastases after a long latent interval. Regression has been carefully investigated by Everson and Cole (1966). In summary, in a review of the literature covering the period 1900–66, they found 64 cases of regression of a primary tumour (including 19 neuroblastomas, 10 carcinomas of the bladder, 9 soft tissue sarcomas, 5 carcinomas of the colon or rectum and 4 carcinomas of the stomach) following either biopsy or manifestly incomplete excision, or, in the case of the bladder tumours, urinary diversion. They also collected 106 cases in which metastases had regressed, usually after excision of the primary tumour; these included 23 patients with carcinoma of the kidney, 19 with neuroblastoma and 15 with malignant melanoma. In patients with multiple subcutaneous melanomatous deposits, Bodenham (1968) made the extremely interesting observation that even though the total number of nodules was increasing, some could be observed to disappear. It is worth noting that this observation, which seems to me to be of great biological importance, was made with nothing more complicated than an ordinary camera and some black and white film.

The sudden appearance and rapid growth of local recurrence and metastases after a long latent interval have also been documented by Everson and Cole (1966), who collected almost 100 cases in which this occurred 10–50 years after removal of the primary tumour. However, instead of referring to their cases I would like to mention two from my own experience, although the latent interval was not quite so long.

The first was a patient who presented with an operable (stage II) carcinoma of the breast and a history of having had a melanoma removed from the foot 3 years previously. She was treated by radical mastectomy and postoperative X-ray therapy. There had been no evidence of local recurrence of the melanoma, or of metastasis, before this treatment, but 6 weeks after operation melanomatous nodules appeared, first in the field of irradiation and then elsewhere, and about 4 months later the patient was dead with metastatic melanoma in the lungs, liver, bone-marrow and brain. It seems clear that in this case the trauma of the operation or the radiotherapy, or both together, brought about some change in the tumour–host relationship, and there is no knowing how long the residual melanoma cells that gave rise to the metastases might have remained dormant had this not occurred.

Often, however, no cause for the sudden appearance of metastases can be discerned. This is illustrated by my second example, a patient who presented with a huge clear cell carcinoma of the right kidney and a history that the left kidney had been removed for a carcinoma 4 years previously. He was treated by transplantation of a kidney from a cadaver, followed by right nephrectomy, in the course of which it was found that the renal vein was invaded by tumour. Despite this, and the fact that he received routine immunosuppressive treatment, the patient remained well for 7 years, without evidence of local recurrence or metastasis. He then began to lose weight and a radiograph of the chest raised a suspicion of pulmonary metastases. Within a few months he was dead with numerous metastases in the lungs and liver.

Tumour cell population kinetics

A tumour is not simply a mass of neoplastic cells but a complex eco-system, which includes neoplastic cells —both living and dead—non-neoplastic cells such as lymphocytes, polymorphs and macrophages and a supporting stroma of vascular connective tissue. Studies of tumour cell population kinetics, based on measurements of the proportion of cells in mitosis after administration of so-called stathmokinetic agents like colchicine and vincristine which cause dividing cells to be arrested in metaphase, and measurement of the proportion of labelled mitoses in autoradiographs of biopsy specimens obtained after injecting tritiated thymidine or of small fragments of tumour tissue treated with this material *in vitro*, have established, first, that with both animal and human tumours only a proportion of the neoplastic cells are proliferating at any given time, and secondly, that many cells are lost either by emigration from the tumour or by cell death. Some of the non-proliferating cells are end-state cells which will die without dividing again; others, referred to variously as dormant or G_0 cells, may resume cycling.

Immunological evidence

Many animal and human tumours possess tumour-associated surface antigens (TAA) which are not present on the surface of normal cells. A subset of these antigens, termed tumour-associated transplantation antigens (TATA), evoke a reaction damaging to the tumour when it is transplanted to a recipient of the same genetic constitution as the autochthonous host (i.e. the individual in which the tumour originated) and some or all of these may evoke a reaction damaging to the tumour in the autochthonous host itself. TAA have been demonstrated by a variety of immunological techniques in many animal and human tumours; so-called carcinoembryonic antigen provides an example of human TAA. The presence or absence of TATA in animal tumours is determined by transplanting the tumour to another animal of the same inbred strain or to an identical twin. The first of the procedures is clearly not available in man and, although the second has been used occasionally, it may be dangerous and is unjustifiable. In animals, however, TATA occur characteristically with tumours induced with chemical carcinogens or viruses and it would be surprising if human tumours of similar origin did not also express antigens of this kind.

The discovery of TATA is the basis of the hypothesis of immunological surveillance of Thomas and Burnet (*see* Burnet, 1970), according to which the incidence and growth of malignant tumours are limited by homeostatic mechanisms of an immunological kind. It is apparent that such mechanisms, if they exist, are far from perfect, otherwise no one would ever get a tumour. Various mechanisms by which a tumour may escape destruction have been postulated. By contrast, some people believe, and it is impossible to disprove, that homeostatic mechanisms of some kind are responsible for the fact that we do not all die of cancer at an early age.

In recent years Burnet's hypothesis has been criticized on the ground that, if it were true, the incidence of spontaneous tumours in congenitally athymic mice, and in patients who are congenitally immunodeficient or have been treated for a long time with immunosuppressive drugs, should be much higher than it is. This criticism tells more strongly against the notion that the T lymphocyte plays a key role in surveillance than against the concept of surveillance itself, and there is a growing body of experimental evidence that macrophages and the as yet not completely identified natural killer (NK) cell may play an important role in surveillance. If surveillance does occur then this has important therapeutic implications. On the one hand, the possibility exists that some forms of treatment may weaken resistance to a tumour; on the other hand, there is the encouraging possibility that it may be possible to exploit and augment natural defence mechanisms by therapeutic means.

The suggestion that it might be disadvantageous to extirpate the axillary lymph nodes in patients with breast cancer was first made by a radiotherapist, Robert McWhirter (1955), though for a reason not directly concerned with my present argument. Today, however, a growing number of surgeons like George Crile and Michael Baum are questioning the wisdom of *routinely* ablating lymph nodes in relation to a tumour by either block dissection or radiotherapy, and the possible harmful effects of chemotherapy on the lymphoreticular tissues is very much in the minds of many people, including, I am glad to say, quite a number of those who use this form of treatment.

The possibility of augmenting natural homeostatic mechanisms by immunological and para-immunological means is being extensively studied in experimental animals and many clinical trials have begun. The procedures used are of two kinds: specific procedures designed to augment the patient's reaction to the TATA of his particular tumour and non-specific procedures which might be expected to increase his capacity to respond to tumours in general. Here, I will mention only one approach, chosen neither at random nor because I can say with confidence that it is the most promising, but because it is the one with which I am most familiar. I refer to non-specific immunopotentiation (in the broad sense of the term) with one particular agent, namely, a killed vaccine of *Corynebacterium parvum.* James Boak and I first demonstrated the anti-tumour effect of this material experimentally (Woodruff and Boak, 1966) when we showed that it would delay the appearance of an isogenically transplanted tumour and it has been confirmed that it potentiates the effect of chemotherapy in dealing with established tumour transplants. The material is normally given intravenously or (in animals) intraperitoneally; it is also highly effective with some tumours when injected locally, but for this effect T lymphocytes are required whereas when given systemically this is not the case. A recent finding is that the effect of chemotherapy may be potentiated by *C. parvum* even in the case of a tumour of spontaneous origin which appears to be virtually non-immunogenic (Woodruff et al., 1978).

It seemed likely, and the available evidence supported this view, that if immunotherapy was going to achieve anything, it would be most effective when the patient's tumour burden had been drastically reduced by surgical excision of the primary tumour, by radiotherapy or by chemotherapy. After an initial study in patients with advanced cancer, therefore, a randomized trial of *C. parvum* as an additional treatment following pulmonary resection for operable lung cancer was set up in Edinburgh. All the patients admitted to this trial had had either a lobectomy or a pneumonectomy for histologically proved bronchogenic cancer and a random sample of the patients received in addition a single intravenous infusion of *C. parvum.* This produces a febrile reaction, which may be quite severe but, if certain precautions are observed, has proved in the experience of ourselves and others to be otherwise well tolerated. While it is too early to draw firm conclusions, since many of the patients with squamous cell lesions in both the *C. parvum* treated and the control groups are still alive, I doubt whether the additional treatment has made very much difference, but it has certainly not proved disadvantageous. The next step, clearly, is to study the effect of repeated treatment with *C. parvum,* since in animal experiments this can be more effective than a single dose. A second trial has therefore been set up, in which thoracic surgeons in a number of centres have agreed to participate.

I see no good reason to advise you at the present time to make radical changes in the way in which you manage patients with cancer, though I am inclined to suggest a fairly conservative attitude towards lymph nodes which are not obviously involved with tumour.

There may well be important changes needed in our management of malignant disease, but it is my guess that excision of primary tumours will continue for a long time to play an important role in the treatment of cancer; it is, however, not a guess but a certainty that this alone in many patients is not enough. Additional forms of treatment are needed to deal with residual disease, even when, indeed especially when, the residual disease is still occult, for that is when treatment is most likely to be successful. The

A GENTLER APPROACH TO THE TREATMENT OF BREAST CANCER

Too often, victims of breast cancer must also suffer the unpleasant side effects of combination cytotoxic chemotherapy.

'Nolvadex' offers a gentler alternative, particularly in post-menopausal women with predominantly soft-tissue disease or metastases. Up to 70% of such patients have responded to 'Nolvadex'[1] yet side effects of treatment are far fewer and much less distressing than with cytotoxic chemotherapy or with additive endocrine therapy.[2]

Moreover, a simple oral dosage means that patients may continue with 'Nolvadex' treatment in their own homes.

1. *Cancer Treatment Reports* (1976), **60**, 1431.
2. *British Journal of Cancer* (1971), **25**, 270

Awarded for the discovery and development of 'Nolvadex'. 'Nolvadex' is a trade mark for tamoxifen citrate.

Bayer

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short-term infusion (5 ml/min to the patient in the recumbent position); thereafter every 4 hours 200,000 KIU slowly i.v.

Precautions
Trasylol may in very rare cases (less than 0.1%) cause hypersensitivity reactions.

Presentation
Ampoules of 100,000 KIU (Kallikrein Inactivator Units)
Ampoules of 200,000 KIU*

development of such new procedures requires both laboratory research and clinical trial; clinical trials are only possible if practising clinicians are prepared to participate. Of course I am not asking you to participate in any trial which you regard as unjustifiable from the point of view of your patients; on the other hand, I urge you not to refuse to participate in a trial simply because it is going to involve some hard work.

Manuscripts and reference style for the *British Journal of Surgery*

Not all papers submitted to our journal or others are accepted. Submission elsewhere may then mean tedious restyling and redrafting. In order to facilitate this inevitable passage of manuscripts from one journal to another, the *British Journal of Surgery* joins with a group of like-thinking journals (1, 2, 3, 4) in asking for its manuscripts to be submitted in uniform style. Details of this, which include the method by which references should be handled in the text, will be incorporated into our Editorial Notices from the June issue. The new reference style is used in this announcement.

The *British Journal of Surgery* will follow the reference style in the list of references of the United States National Library of Medicine, which is also used in *Index Medicus*. Some details are given in our Editorial Notices but authors are advised (as they are in these notices) to refer to *British Medical Journal* 1979; 1: 532–5 or *Lancet* 1979; 1: 428–31 and to obtain copies of the Vancouver Declaration (available from the Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR, at a cost of 50 p including postage).

The new style will come into use in January 1980 for Volume 67 of the *British Journal of Surgery*. Authors are requested to change their form of submission *now* to that of the new style.

Wound drainage following radical mastectomy: the effect of restriction of shoulder movement

T. J. FLEW*

SUMMARY

A randomized prospective clinical trial has been performed to determine the effect of temporary immobilization of the shoulder on wound drainage following radical mastectomy. In 64 patients admitted to the trial the mean volume of drainage was reduced by 40 per cent in those who had shoulder movement restricted for the first 7 days after operation when compared with the group in whom early arm exercises were encouraged. The mean drainage time was reduced by 29 per cent. Shoulder immobilization did not result in increased shoulder stiffness, although there was an increased incidence of mild lymphoedema of the arm.

SUBCUTANEOUS fluid collections may complicate any operation in which large skin flaps are raised. They are frequently encountered in the postoperative care of mastectomy patients, especially after the radical operation.

The traditional practice used to be to allow the fluid to escape via one or more open drains into a thick layer of dressings held in place by careful strapping or bandaging. Compression was used to inhibit the further formation of fluid and attempts were sometimes made to obliterate the dead space and to hold the flaps still by means of sutures. Orr (1951) used tension sutures tied over rubber tubing to hold the flaps against the chest wall, Keyes et al. (1953) tried multiple silk sutures together with drains, while Larsen and Hugan (1955) stitched down the flaps with up to fifty subcutaneous cotton sutures and advised extensive early shoulder movement. These methods were not without complication and were abandoned with the introduction of continuous closed suction drainage. Here, suction is usually maintained for several days until the drainage has almost ceased and the potential dead space is obliterated by adherence of the skin flaps to the deeper structures. Murphey (1947) was the first to describe suction drainage after radical mastectomy, and its superiority over open drainage was shown by Morris (1973) and by Bourke et al. (1976). In particular, the frequency of dressings and length of time until the removal of drains are reduced, and in Morris's series there was reduction in delayed wound healing and in the length of stay in hospital.

Large skin flaps would be expected to become more rapidly adherent to the underlying structures if they were held relatively immobile rather than subject to repeated movement, with consequent reduction in fluid formation. Nevertheless, there is no conclusive evidence that this is so. Riddell (1948) advocated discouragement of all movements at the shoulder joint following radical mastectomy because 'too early movement has caused separation of the skin edges of the flaps and increased the liability to serum collection, without any compensating advantage in the ultimate range of movement at the shoulder joint'. The majority of surgeons, however, probably recommend early arm movements because of the potential risk of developing shoulder stiffness. This procedure was standard in this unit, but considerable problems arose because of persistent wound drainage continuing sometimes two or more weeks after operation.

This controlled clinical trial was carried out to determine the effect of temporary restriction of shoulder movement on the volume and duration of wound drainage following radical mastectomy. An assessment was also made of the effect of this regimen on the incidence of shoulder stiffness and lymphoedema of the arm.

Patients and methods

During 8 months in 1973, 64 consecutive patients undergoing radical mastectomy for early breast cancer were admitted to the trial. All patients were nursed in the same ward of the Guy's Breast Unit at New Cross Hospital. The operations were all modified Halsted radical mastectomies performed to a standard technique by six surgeons. Diagnosis was confirmed histologically by open biopsy, either as a separate procedure or by frozen section as a preliminary to mastectomy. Elliptical skin incisions were marked out in ink and the skin flaps infiltrated subcutaneously with a solution of 1 : 400 000 adrenaline in saline to reduce haemorrhage. The flaps were cut to include some subcutaneous fat, and mastectomy performed with complete axillary node clearance together with *en bloc* removal of pectoralis minor, and a proportion of the sternal head of pectoralis major depending on the site of the tumour. Haemostasis was achieved by diathermy, with occasional catgut ligatures. The wound was then irrigated with hot (48 °C) sterile distilled water, with the objective of lysing any seeded malignant cells. Three Redivac drains were introduced with a trocar through the lower flap, one passing beneath each flap and one into the axilla, and sutured loosely in place to the chest wall with 2/0 catgut. The wound was sutured with interrupted silk by the method of 'halving' to match the flaps equally, sprayed with Nobecutane and covered with a light gauze and wool dressing held in place with Netelast. Skin grafting was not performed. The three drainage tubes were connected to vacuumed bottles, and after release of the clamps the flaps were gently massaged to evacuate any blood which had collected before the patient left the operating table.

At this stage the patient was randomly allocated to the trial by drawing an envelope from a box. On return to the ward, those patients who drew the 'fixed' option had the shoulder on the side of operation held relatively immobile by a triangular bandage. The bandage enclosed the upper arm and was tied around the waist. This prevented abduction at the shoulder whilst allowing a certain amount of internal and external rotation but, by leaving the forearm free, did not greatly inconvenience the patient. For those who drew the 'free' option the arm was left unrestricted, and arm movements commenced under the guidance of a physiotherapist from the second postoperative day. On the seventh day the triangular bandage was removed from the patients in the 'fixed' group and the same programme of arm movements was begun under supervision.

In both groups the wool was removed from beneath the Netelast on the third postoperative day, leaving a light gauze dressing covering the wound. Provided wound healing was satisfactory, one-third of the sutures were removed on the

tenth day, one-third the next day and the remainder on the twelfth day. The drainage bottles were changed as often as necessary, and the volume of fluid in each was measured daily. Each drain was removed when it had produced 20 ml or less on 3 consecutive days. At subsequent inspection if a seroma had collected beneath the flaps it was aspirated by means of a needle and vacuumed tube (Vacutainer). This was repeated as required on an in- or outpatient basis until the reaccumulation of fluid had ceased. The total volume of drainage, the length of time until the removal of the last drain and the number and volume of aspirations were recorded.

All patients were assessed preoperatively, 2 weeks postoperatively and again as outpatients 1 month and 4 months after discharge from hospital. The wounds were inspected at least every 3 days until discharge from hospital, and if not then healed they were checked again weekly until healing was complete.

The following data were recorded:

Shoulder movements

1. Abduction and elevation (0–180°).
2. Internal and external rotation with the upper arm abducted to horizontal and the elbow flexed to 90°.

A note was also made of subjective shoulder stiffness and of any additional physiotherapy required following discharge from hospital.

Lymphoedema

The circumference of both arms was measured at points 20 cm above and 10 cm below the olecranon.

Wound healing

1. Delay in healing: (*a*) breakdown of the wound, defined as separation of the wound edge over any length; (*b*) necrosis of the flaps, judged as any area of sloughing greater than 5 mm in diameter at 14 days; (*c*) delay in removal of sutures beyond 12 days.
2. Wound infection, defined as purulent discharge from the wound, pus that could be aspirated, or cellulitis of the skin flaps associated with a pyrexia greater than 38 °C.
3. Wound haematoma, defined as a collection of fluid beneath the flaps which, when aspirated, appeared to be frank blood.

Clinically apparent postoperative chest infection and deep vein thrombosis were also recorded, as were any other significant complications.

The majority of patients received postoperative radiotherapy. Those with clinically uninvolved axillary nodes were part of another trial then in progress to compare radical mastectomy with wide excision of the lump in the treatment of 'early' breast cancer, and all received radiotherapy. Radiotherapy was only given to those with clinically malignant nodes if involvement was confirmed histologically. After the wound was fully healed, treatment was given to the axilla, supraclavicular triangle and internal mammary chain, in a dose of 3000–3300 rad given over 3 weeks. The percentage of patients who received radiotherapy was similar in the two groups (*Table I*), and all had completed treatment by the time of their follow-up examination at 4 months.

Results

Sixty-four patients were admitted to the trial. In the group with the arm unrestricted ('free') there were 29 patients whose age range was 28–77 years (mean 53·5 years). In the group with shoulder restriction ('fixed') there were 35 patients whose age range was 27–72 years (mean 51·4 years). *Table I* shows that the two groups were similar with respect to tumour size, lymph node involvement, radiotherapy and subsequent recurrence, thus excluding bias. The results were assessed statistically using Student's t test and the χ^2 test with Yates's correction.

Wound drainage (Table II)

In the 'free' group mean drainage volume was 1203·1 ml and mean total drainage time (including aspirations) 16·4 days, compared with 725·4 ml and 11·7 days respectively in the 'fixed' group of patients. These reductions in drainage volume and duration are significant ($P<0{\cdot}01$ and $P<0{\cdot}05$ respetiveely). Time postoperatively until the removal of the last drain was reduced from a mean of 13·7 days in the 'free' group to a mean of 11·2 days in the 'fixed' group, and there was a small reduction in the length of stay in hospital, but these differences are not statistically significant.

Table I: COMPARISON OF TRIAL GROUPS

	Fixed	Free
No. of patients	29	35
Age (yr)		
Mean	53·5	51·4
Range	28–77	27–72
Involved axillary nodes		
No. of patients	13 (44·8%)	15 (42·9%)
Mean no. of nodes	2·5	1·9
Postoperative radiotherapy		
No. of patients	21 (72·4%)	24 (68·6%)
Tumour recurrence at March 1978 (4½–5 yr)		
Recurrence	10 (34·5%)	12 (34·3%)
Died	6 (20·7%	8 (22·9%)

Table III: SHOULDER ABDUCTION AT 4 MONTHS

	Shoulder abduction	
Group	Limitation>30° (no. of patients)	Mean limitation (degrees±s.e.)
Fixed (n = 29)	8	19·8±3·3
Free (n = 34)	13	21·2±3·6

The differences are not significant.

One patient in each group had a pocket of fluid aspirated before removal of the last drain. Following removal of all drains, 7 patients in the 'free' group had a total of 33 aspirations up to 60 days postoperatively, compared with only 2 patients requiring a total of 4 aspirations up to 18 days postoperatively in the 'fixed' group.

Shoulder stiffness (Table III)

One patient in the 'free' group died from metastatic disease just before her 4-month assessment was due and is therefore not included in the follow-up. No patient had restricted shoulder movement before mastectomy. There was no postoperative limitation

Table IV: LYMPHOEDEMA AT 4 MONTHS

No significant differences.
* Patient died with metastases 4 months post-mastectomy.

of internal or external rotation at the shoulder in any patient at 4 months. Early in the postoperative phase there was considerable impairment in arm abduction in the 'fixed' group, but at 4 months there was no significant difference between the two groups. Only 1 patient, who had not had her arm restrained, had stiffness of the shoulder sufficient to require physiotherapy as an outpatient.

Lymphoedema (*Table IV*)

At 4 months there was mild lymphoedema (1·0–2·5 cm) in 15 patients in the 'fixed' group, compared with only 7 in the 'free' group ($P < 0·02$). There were 3 patients in each group at this time with moderate swelling (2·5–4·5 cm) and only 1 patient had severe lymphoedema (>4·5 cm). This patient, from the 'fixed' group, had only mild swelling of the upper arm, but had a 5·1-cm increase in forearm circumference. Overall, there was a mean increase in forearm circumference of 0·83 (±0·25) cm in the 'fixed' group compared with a mean increase at the same site in the 'free' group of 0·22 (±0·21) cm at 4 months ($P < 0·1$).

Other complications (*Table V*)

There was no significant difference in the rate of delayed wound healing beyond 12 days in the group that commenced arm exercise early, and no patient had suture removal delayed. The rates for other complications were similar, but the numbers were small.

Discussion

This trial has demonstrated that by limiting shoulder movement for 7 days postoperatively the amount of fluid drained from a radical mastectomy wound can be reduced by an average of 40 per cent, while the length of time until fluid formation ceases is reduced by about 29 per cent. As well as being a consequence of stabilization of the skin flaps, this is probably also due in part to a lessening of drainage from severed axillary lymphatics.

The results also suggest that an increase in the incidence of lymphoedema might be anticipated from routinely employing this method of postoperative care. The incidence of post-mastectomy lymphoedema varies in different series from 8 to 80 per cent (El-Kharadly and Enein, 1965) and is principally affected by the extent of surgery, the type and dose of radiotherapy and the incidence of infection. Atkins et al. (1972), in a series of 90 patients also treated at Guy's Breast Unit, reported an incidence of 81 per cent 3 months after radical mastectomy, 71 per cent being classed as mild (0–2·5 cm), 6 per cent as moderate (2·5–4·5 cm) and 4 per cent as severe (more than 4·5 cm). All their patients had postoperative radiotherapy and were given active arm exercises the day after mastectomy. The results of the present trial are of the same order, but suggest that there is a significant increase in lymphoedema, at least to a slight degree, as a result of restriction of arm movement for 1 week postoperatively. Four months after discharge from hospital there was a mean increase of 3 mm in circumference of the upper arm and of 6 mm in the forearm. The reason for this is obscure, though reduced arm movements may lead to interference with the pumping action of the muscle on venous and lymph flow, and may promote axillary vein thrombosis. Guthrie and Gagnon (1946) advocated mobilization of the arm to prevent post-mastectomy lymphoedema, and noted a high incidence of swelling in those with poor function, but did not show which was cause and which effect.

With regard to shoulder mobility, it is generally advised that movements should be commenced early to prevent stiffness. Healey (1971), in a prospective study of 271 patients, found that 34 per cent had some limitation of shoulder movement 1–4 years after radical mastectomy, 8 per cent being unable to abduct to 90°. Some of them had performed early exercises under the supervision of a physiotherapist, others had had no formal instructions. Moreover, Pollard et al. (1976), in a study of 192 patients having both radical and simple mastectomy, found that early physiotherapy resulted in significantly better shoulder movements than were obtained in those patients advised not to move the arm until suture removal at 7–10 days. These patients, however, were not randomly allocated to the two treatment options. The present trial does not confirm that any increased shoulder stiffness results from limiting shoulder movement after operation.

It is concluded that active shoulder movement immediately after mastectomy should not be advised. Drainage is increased in volume and duration, without affecting eventual shoulder mobility. The liability to lymphoedema may be increased but is limited in extent.

Acknowledgements

I wish to express my thanks to Mr J. L. Hayward for his help and advice in performing this trial, and to the nursing staff of the Hedley Atkins Unit at New Cross Hospital. This study was undertaken during the course of an Imperial Cancer Research Fund Fellowship.

PULSE VOLUME RECORDER (PVR®)*

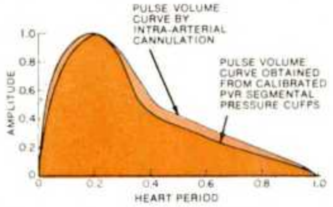
The NON-INVASIVE Clinical Vascular Laboratory

An Extensively Documented Clinical Procedure for the Quantitative Evaluation of Peripheral Vascular Disease:

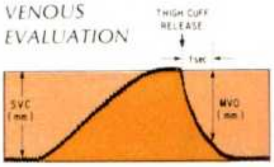
Arterial — Venous — Cerebral

Excellent Long-term Reproducibility and Calibrated Accuracy by Quantitative Segmental Cuff Technique

Ophthalmic artery pressure is read directly on the OPG Attachment of the PVR for the evaluation of collateral circulation to each eye, and its respective cerebral hemisphere.



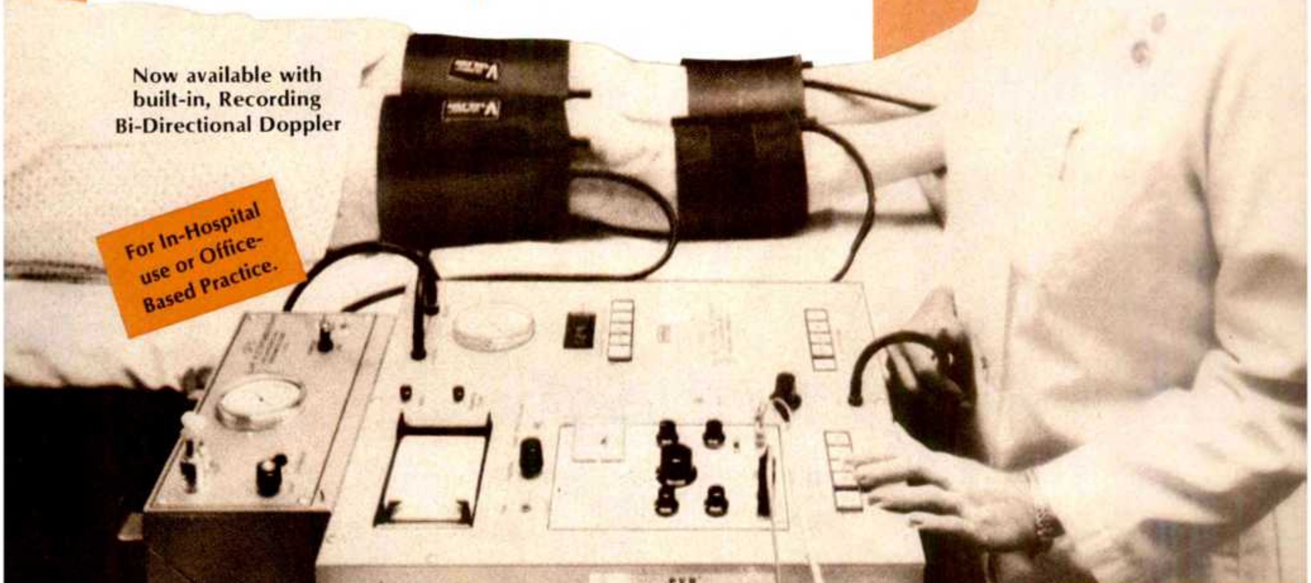
Comparison of pressure contours obtained with the PVR and direct cannulation of the common femoral artery.



A 15-point scale provides approximately 5% false (+) and 2% false (-).

Total Segmental Perfusion (primary vessel plus collaterals) is accurately documented at the thigh-calf-ankle-metatarsal level and digits. The built-in Doppler facilitates the measurement of pressures along the arterial tree.

The COMBINED information of segmental PVR recordings and systolic pressure gradient establishes a clinically accurate picture of functional perfusion.



Now available with built-in, Recording Bi-Directional Doppler

For In-Hospital use or Office-Based Practice.

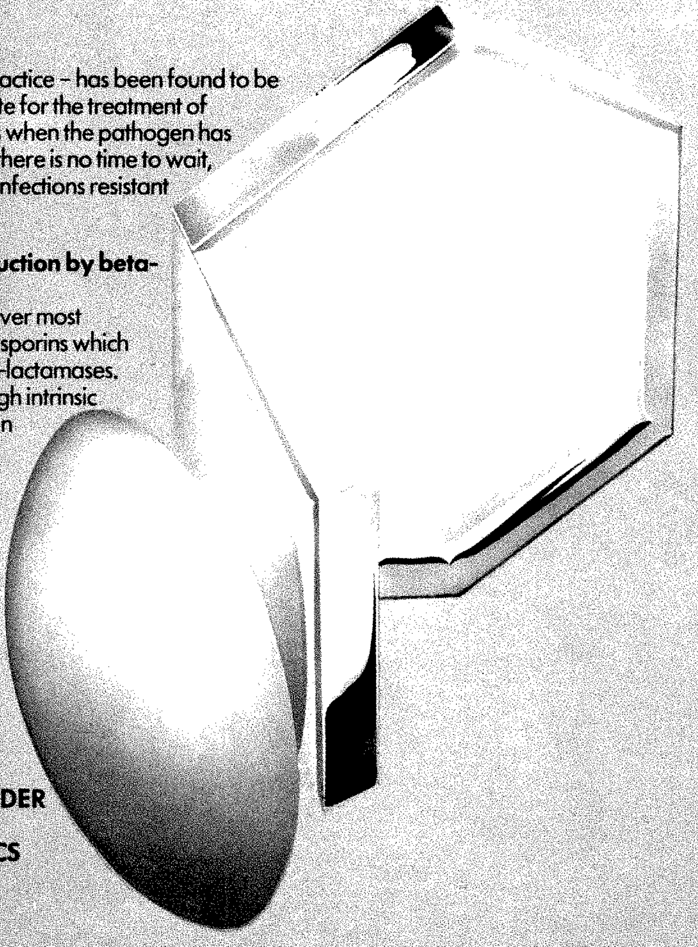
A MAJOR ADVANCE IN ANTIBIOTIC THERAPY

Already used widely in
● serious infections

INJECTABLE

ZINACEF

cefuroxime sodium



Zinacef – in hospital practice – has been found to be particularly appropriate for the treatment of serious acute infections when the pathogen has not been isolated and there is no time to wait, and in difficult to treat infections resistant to other antibiotics.

Zinacef resists destruction by beta-lactamases
A distinct advantage over most penicillins and cephalosporins which are destroyed by beta-lactamases. This, together with a high intrinsic activity gives Zinacef an extended clinical spectrum.

Zinacef is effective against:
- **most common pathogens**
- **many uncommon pathogens**
- **multi-antibiotic resistant pathogens**

ZINACEF, A BROADER SPECTRUM THAN MOST ANTIBIOTICS

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 grams and infusion pack of 1·5 grams. All containing cefuroxime as cefuroxime sodium.
Indications
Serious bacterial infections, especiall where the organisms have not yet been identified.
Conditions include:
Chest infections
Septicaemia
Soft-tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Ear, nose and throat infections
Meningitis
Gonorrhoea
Dosage
Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 grams t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary, giving total doses of 3 grams to 6 grams daily.
Infants and Children: 30 to 100mg/kg/ day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in two or three divided doses.
Gonorrhoea: Single dose of 1·5 grams (2 x 750mg i.m. into different sites).
Contra-indications
Hypersensitivity to cephalosporins.
Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria. Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine. As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage shoul be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.
Side effects
Adverse reactions are rare and generally mild and transient, e.g., rashes, gastro-intestinal disturbance, candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).
Storage
Protect from light.
Product Licence number: 4/0263
Price to Hospital (exclusive of VAT)

5 x 250mg	£0·70 per vial
5 x 750mg	£2·10 per vial
1·5 grams	£4·20

The management of suspected tumours of the colon: the role of colonoscopy in general surgery

S. T. D. McKELVEY*

SUMMARY

The role of colonoscopy in the management of 100 cases of suspected large bowel tumour is described. Forty out of 47 patients with an equivocal barium enema examination were satisfactorily examined and the possibility of a tumour being present was either confirmed or refuted. Examination of 30 patients with otherwise unexplained blood loss from the bowel revealed the cause in 50 per cent of them. Twenty-nine patients had pedunculated polyps which were snared and removed, thus avoiding laparotomy and colotomy.

The problem of distinguishing tumours from other lesions or retained faeces by radiology arises most often in the sigmoid colon. This segment is easily examined using a short flexible endoscope. General surgeons taking up colonoscopy will find a 1-m single-channel instrument convenient to use and capable of reaching approximately 90 per cent of colonic tumours that require further investigation or endoscopic resection. Facilities for the examination of the whole colon should be available in established endoscopy units.

FIBREOPTIC colonoscopy has not been widely practised by general surgeons in the United Kingdom because it is considered to be both difficult and time-consuming. Once the technique is mastered, however, colonoscopy often clarifies the diagnosis in colonic disease and may prevent an unnecessary laparotomy for suspected tumours (Hunt et al., 1975) or unexplained rectal bleeding (Waye, 1976; Teague et al., 1978). Colonoscopic polypectomy has transformed the management of patients with adenomatous polyps (Wolff and Shinya, 1973; Williams et al., 1974).

This paper presents the results of colonoscopy performed by a general surgeon in the investigation of patients with suspected large bowel tumours.

Patients and methods

One hundred patients with suspected large bowel tumours were examined. They were aged 20–86 years with a mean age of 56 years. There were 36 men and 64 women. The indications are given in *Table I*.

Patients were admitted 24 h before examination and put on a fluid diet. Except in frail patients, who were given a reduced dose, 142 mg of sennosides (X-Prep) were given orally in order to empty the colon. Two hours before the examination an enema of oxyphenisatin (Veripaque) was given. Each patient was given a premedication of diazepam, 10 mg orally, and most patients received a further 10 mg of diazepam and 50 mg pethidine intravenously before the endoscopy. Intramuscular cyclizine (50 mg) was given to minimize any nausea or retching. Three patients were examined under general anaesthesia.

Diagnostic colonoscopy was performed using single-channel instruments (ACMI Model F9L, Olympus Model CFMB3), while polypectomy was performed through a twin-channel endoscope (Olympus Model TCF2L). All examinations were carried out in the X-ray department using fluoroscopic control.

Table I: INDICATION FOR COLONOSCOPY IN 100 PATIENTS

Equivocal barium enema examination	47
Unexplained rectal bleeding	30
Polypectomy	23
Total	100

Table II: PATIENTS WITH EQUIVOCAL BARIUM ENEMA EXAMINATIONS (47 CASES)

Referred with rectal bleeding	5
	33
Outcome	
Polyps removed	29
'Polyps' not found	1
Malignant polyp—colectomy	1
Small polyps not fulgurated	2
	33

Results

Table II shows the results in 47 patients who had had an equivocal barium enema examination. In 26 patients the radiographs suggested the possibility of a carcinoma and polyps were suspected in the other 21 patients. In 40 out of the 47 patients it was possible to resolve the diagnostic problem by the finding of tumours in 9 and of a benign condition or a normal colon in 31. In 7 patients a diagnosis was not made; a narrow stricture which could not be entered was present in 2 patients and it was not possible to advance the instrument sufficiently in the other 5 patients. In 1 patient examined under a general anaesthetic a perforation occurred, which was recognized immediately and sutured at laparotomy.

* The Royal Victoria Hospital, Belfast.

Examination of 30 patients with either frank rectal bleeding or anaemia due to blood loss showed a lesion in 18 patients; in the remaining 12 no colonic lesion was found (*Table III*). Patients with frank rectal bleeding gave a high yield, with positive findings in 16 out of 22 patients, although in 2 patients found to have diverticular disease and 1 patient with mild ulcerative colitis, a causal relationship between the pathology and the symptoms was doubtful. There were positive findings in only 2 out of 8 patients with occult bleeding. In one of these patients a pedunculated sigmoid polyp was removed and accepted as the cause. Two years later the patient was found to have a carcinoma of the transverse colon, despite a check barium enema examination 6 months after polypectomy.

Polypectomy was successful in 29 out of 33 patients (*Table IV*). Twenty-nine pedunculated polyps were snared and removed. In addition, 17 small sessile polyps were found and the majority of them were fulgurated. One patient had a malignant sigmoid polyp requiring colectomy. Six months after polypectomy in one patient, a further large polyp was found which had not been detected on the first occasion. The site of polyps removed is shown in *Fig.* 1.

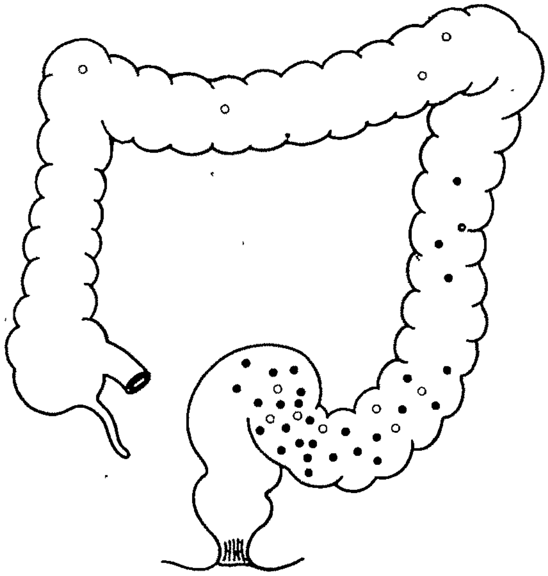

Fig. 1. The site of polyps removed in 29 patients. Pedunculated polyps are shown as closed circles and sessile polyps as open circles.

Discussion

Endoscopy of the colon may be considered as an extension of the practice of endoscopy of the rectum, which has been widely used by general surgeons. The technique of colonoscopy is relatively new and more difficult than that of sigmoidoscopy and this has inhibited its adoption in the management of colonic disease. As experience increases, and as improved instruments became available, it is probable that colonoscopy will be more widely used in the future.

In surgical practice colonoscopy is of most value in the management of patients with suspected tumours of the colon. The radiograph may show a lesion, suggestive of tumour, that is difficult to distinguish from benign disease or retained faeces. Sometimes the clinical problem is rectal bleeding not explained on proctosigmoidoscopy or after barium enema examination. If the radiology is technically satisfactory the surgeon can choose between colonoscopy or a laparotomy. The latter may produce equivocal findings and may result in an unnecessary operation.

Only 9 of the 40 patients in this series who were satisfactorily colonoscoped following an equivocal barium enema examination were found to have tumours. This suggests that clinicians were referring only very doubtful cases. Nevertheless, it is rewarding to be able to reassure the majority of patients that no tumour is present. The 2 patients who were found to have narrow strictures of the colon, which could not be entered, were submitted to laparotomy and had sigmoid colectomy for diverticular disease.

Rectal bleeding, the cause of which has not been demonstrated by sigmoidoscopy and barium enema examination, must be further investigated. In two-thirds of our patients with frank bleeding, colonoscopy revealed lesions that seemed to be the source of the bleeding. The discovery of a sigmoid carcinoma in 4 patients prompted a review of the previous investigations. In 3 of the 4 patients a single contrast enema had been performed in a peripheral hospital and the other had had a double contrast enema which had been carried out in a teaching hospital, although the appearances of the films suggested that inadequate bowel cleansing had been a major factor in obscuring the tumours. Colonoscopy for occult rectal bleeding is less productive but it may reveal important lesions in some patients (Waye, 1976). Teague and his co-workers (1978) emphasize the importance of total colonoscopy as the finding of a polyp in the distal colon may only have importance as a herald of a more proximal carcinoma. If the colon is normal, attention should be diverted to the stomach and small bowel.

Colonoscopic polypectomy represents a major advance over the traditional laparotomy/colotomy. The morbidity and mortality of colotomy are eliminated and the time off work required is reduced from 2–3 months to 2–3 days. In the 29 patients undergoing polypectomy in this series, no major complications arose, though in larger series a small incidence of haemorrhage and perforation is reported (Geenen et al., 1974; Graham and Eusebio, 1977). In one patient tenderness in the left iliac fossa was present for 72 h after fulguration of a small polyp with an insulated probe. The risk of full-thickness cautery can be avoided by the use of the hot biopsy technique (Williams, 1973) and all small sessile polyps can now be safely destroyed. Examination of at least the left colon, and perferably of the whole colon, should be carried out in conjunction with polypectomy as it is usual to find more polyps than were demonstrated by the barium enema examination.

The difficulties and dangers of colonoscopy cannot be lightly dismissed. Meticulous bowel preparation is essential, but this is no more than the requirement for good radiology. In this series, vigorous purgation with sennosides followed by an oxyphenisatin enema was found to be efficient, though sometimes distressing to the patient. Patients undergoing polypectomy should always be admitted for 48–72 h, but patients having examination only may be allowed home on the same day. Sedative and analgesic drugs, such as diazepam and pethidine, should be given, as most patients experience discomfort during the procedure.

Experience in handling upper gastrointestinal endoscopes is desirable before commencing colonoscopy, though there are problems in instrument insertion that are peculiar to colonoscopy. Passing the instrument from the sigmoid colon into the descending colon and around the hepatic flexure presents the most difficulty due to the great mobility of the sigmoid colon and the transverse colon. Various manoeuvres are described in the literature to overcome these difficulties (Williams and Teague, 1973). If problems persist, it is advisable to visit specialist centres or attend courses organized by the British Society of Digestive Endoscopy. Apprenticeship to an experienced colonoscopist would be ideal.

Major complications, such as full-thickness perforation, were reported in 0·9 per cent of a large series of patients (Geenen et al., 1974). Perforation is more likely to occur in the early experience of the colonoscopist, and when the examination is carried out under general anaesthesia. The endoscopist should aim to keep a view of the lumen at all times and should use the slide-by technique over short distances only. Pressure from the side of the instrument may cause stretching and possibly a tear of the apex of a large loop. These mishaps are unlikely to occur if the patient's complaint of pain is heeded, thus emphasizing the need to avoid the use of general anaesthesia. Polypectomy carries the additional risk of coagulation of the wall of the bowel and bleeding from the transected stalk. If the diathermy current is passed at a low setting at first and gradually increased until a band of coagulation appears which is equal in width to the diameter of the stalk, then bleeding is not likely to occur after separation. Coagulation of the bowel wall is prevented by not snaring too close to the base of the stalk and also by moving the position of the polyp between each short burst of current so that the opposite wall of the bowel is not damaged by current passing through the apex of the polyp. The coagulation of small sessile polyps is safe if a pseudopedicle is first created by pulling on the polyp using insulated biopsy forceps (Williams, 1973).

A long single-channel colonoscope is suitable for virtually all problems amenable to colonoscopy. However, as up to 90 per cent of 'surgical' problems are within reach of a short colonoscope (1 m), there is probably a case for the novice colonoscopist starting with a short single-channel instrument because it is easy to manipulate. A twin-channel colonoscope is helpful in polypectomy; it is sometimes more difficult to pass than a single-channel instrument, but has the advantage of leaving the suction channel free during snaring and allowing the polyp to be grasped before the stalk is completely severed.

General surgeons, whose main interest is gastroenterology, should use colonoscopy in the management of patients with large bowel disease. The increased accuracy in diagnosis and the ability to exclude carcinoma and remove polyps without laparotomy amply repay the expense and training required to master this rather difficult technique.

Acknowledgements

I would like to thank Professor Roy for his encouragement in this work and the clinicians who referred the patients to me. I would also like to thank Sister Coe, Sister Rice and Miss Linda Sherwin for their help. The Royal Victoria Hospital Working Men's Committee generously donated the twin-channel colonoscope.

Cancer of the large bowel in a defined population: Canterbury, New Zealand, 1970–4

R. J. STEWART, R. A. ROBSON, A. W. STEWART, JOANNA M. STEWART, AND W. A. A. G. MACBETH*

SUMMARY

A total of 1024 new cases of cancer of the large bowel occurred in Canterbury, New Zealand (population 400 796), in the 5 years 1970–4. Of these, 992 were diagnosed before death and are reviewed in this paper.

The high incidence of this disease in New Zealanders of European origin is illustrated. A significant difference in site distribution of primary tumours between the sexes was found, with a female preponderance of cancer of the proximal colon gradually changing to a male preponderance of cancer of the rectum. In all, 61·5 per cent of the patients had lymph node metastases or advanced disease at the time of diagnosis or treatment. Largely as a consequence of this, only 65 per cent were able to have potentially curative treatment.

The estimated crude 5-year survival rate of the whole group was 32·7 per cent (relative rate 42·8 per cent) and the crude 5-year survival rate after potentially curative surgery was 48·4 per cent (relative rate 62·4 per cent).

The results are compared with those of other authors. They emphasize the generally unsatisfactory outcome of treatment.

It has been a conventional wisdom among doctors that large bowel cancer is a 'good tumour' which can often be cured by surgery. This attitude has been strengthened by relatively favourable reports of treatment based on the practice of special hospitals (Bussey and Morson, 1963; Wilson and Beahrs, 1976) or of individual surgeons (Morgan, 1965; Turnbull et al., 1974; Hughes, 1976). Nevertheless, as well as being the most prevalent major neoplasm in many Western countries (Higginson and Maclennan, 1973), the disease is drawing level with cancer of the lung as the major killer, at least in New Zealand (*New Zealand Health Statistics Report: Cancer Data*, 1976). Slaney (1971) showed that when a whole population is considered, the spectrum of disease and the results of treatment are less favourable than generally realized. Unfortunately, such population-based studies are uncommon and most reports concern the work of particular institutions where a variable and generally unknown degree of case selection has occurred.

The aims of this study are twofold. First, to survey cancer of the large bowel as it occurred recently in a defined Western population, with special reference to incidence, pathological spectrum, management and survival. Secondly, to give our students and colleagues an overview of the problem as it affects the people amongst whom they live and work.

Patients and methods

Most of the information contained in this paper came from the records of the National Cancer Registry (NCR), which is an organ of the National Health Statistics Centre, Department of Health. Abstracts of the records of cancer patients (except those with simple skin neoplasms) are forwarded to the registry by specially trained registrars based in the major public hospitals. The NCR estimates that the national registration rate was 92 per cent in 1971 and close to 100 per cent by 1974. However, in Canterbury it may have been somewhat better during this period, because of the centralized hospital service and the enthusiasm of the cancer registrars. The data are reviewed and further information is obtained from clinicians or pathologists if records are inconsistent or incomplete. In addition, the registry receives mortality returns from all death certificates. A fuller account of the activities of the NCR is given by Foster (1977).

The information was analysed with the aid of a PDP 11/70 digital computer. The following statistical methods have been used in this study: log rank test (LRT) (Peto and Pike, 1973), Kolmogorov–Smirnov two-sample test (K–S), Mann–Whitney U test (MWU) and the life-table method to calculate survival rates (Cutler and Ederer, 1958). In addition to crude survival rates, we have given, where appropriate, the relative survival rates (Ederer et al., 1961) defined as the percentage ratio of the crude survival rate for the patient group to the rate expected of people in the general population similar with respect to age, sex, race and period of observation. (This statistic is sometimes termed actuarial or corrected survival.) The 5 per cent level of significance has been adopted.

The population

The patients under study resided in the North Canterbury, Ashburton or South Canterbury Hospital Districts. This region approximates to the old Province of Canterbury, which is a natural geographical zone on the eastern side of the South Island of New Zealand. The population, as determined in the census of 1971, was 400 796, with 198 624 males and 202 172 females (*The New Zealand People 1971*, 1976). The age distribution is closely similar to that of the whole population of New Zealand and the hypothetical one proposed for European societies by Doll and Cook (1967).

Most Canterbury people are of European descent (95 per cent). The Polynesian community is smaller than in other parts of the country (3 per cent) and mostly consists of Maoris. Although New Zealand is an agricultural nation, 83 per cent of this population live in cities and towns, mostly in Christchurch, which had an urban population of 275 000 in 1971 There is significant mobility, with 32 per cent of the people having changed their address between the 1966 and 1971 censuses. However, this mostly occurred within the region and involved younger people.

Results

Incidence

In the 5-year period 1970–4, 1024 people were first diagnosed as having large bowel cancer. Of these, 25 cases were discovered at post-mortem and will be considered separately. A further 7 patients with carcinoid tumours of the appendix have been excluded because of the distinctive natural history of this disorder. This leaves 992 patients who were diagnosed before death. There were 607 cases of colonic cancer (261 men; 346 women), 347 cases of rectal cancer (201 men; 146 women) and 38 cases with cancer of the

* According to method of Doll and Cook (1967) based on 'world' population of Segi (1960). Expressed as cases per 100 000 people per year.

† Rates given by Higginson and Maclennan (1973).

large bowel, site unspecified (22 men; 16 women). The overall incidence of large bowel cancer based on this series is 49·5 per 100 000 population per year.

Age-specific incidence: The incidence by decade of life is depicted graphically in *Fig.* 1 and compared with the total numbers by decade. It shows that incidence rises steeply with age, though the largest numbers of patients are aged between 60 and 70. The decline in incidence in the tenth decade is of uncertain significance for there were only 9 patients in this category.

Standardized incidence: Because age distribution often differs between populations (and between the sexes), the observed incidence may be misleading when used for comparisons. More reliable information can be obtained by using the standardized (age-adjusted) incidence (Doll and Cook, 1967), whereby the incidence is adjusted to that which would apply if the population had the age distribution of the hypothetical world population of Segi (1960). The standardized incidence per 100 000 per year by major site and sex based on this series is compared with some other populations in *Table I*. The figures illustrate the high incidence of large bowel cancer in New Zealand and suggest that there may be a higher rate of colonic cancer in New Zealand and North America than among some European populations.

Sex incidence: *Table I* also compares the incidence of colonic and rectal cancer in males and females. In each population given, the incidence of rectal cancer in men is substantially higher than that in women. In contrast, there is an equal incidence of colonic neoplasia (the greater numbers of females can be explained by their relative longevity).

Racial incidence: There was only one Maori patient in the group. The incidence of large bowel cancer in New Zealand Maoris is approximately 20 per cent of that among Europeans (*New Zealand Health Statistics Report: Cancer Data*, 1974). On this basis, one would have expected about 5 Maori patients.

Post-mortem diagnosis: Twenty-five patients were found, incidentally, to have large bowel cancer at post-mortem. In 1972, the national post-mortem rate was 31 per cent (*Trends: Health and Health Services*, 1975). The separate figures for Canterbury are not yet available. The total number of patients with unsuspected large bowel cancer may therefore have been approximately 80 in this 5-year period and inclusion of these cases in the incidence figures would increase them slightly.

Is the incidence changing? Some information on this is available on a national basis. The NCR uses a statistic called the standardized mortality ratio (SMR) which relates death rates from any cause to the respective rates applying in 1950–2. The mortality figures for large bowel cancer show no consistent change in the past 20 years (*New Zealand Health Statistics Report: Cancer Data*, 1974).

Pathology

Histology: Histological examination of the tumour was obtained in 922 of the 992 patients, i.e. 93 per cent. Of these, 96·5 per cent were adenocarcinomas, 2·5 per cent were carcinomas of unspecified type (our pathologists consider that these were mostly anaplastic adenocarcinomas), 0·9 per cent were squamous cell or basaloid carcinomas (all in the rectum or anal canal), and there was one leiomyosarcoma. Cytological grading was not recorded.

Site distribution: The sites of the primary tumours were classified according to the *International Classification of Diseases, Eighth Revision* (1967), except that site 153.8 (colon unspecified) and 153.9 (intestine unspecified) have been combined as 'large intestine unspecified', because of doubt about the way in which these categories were constituted. Most of such patients either had advanced disease or were incompletely documented.

The percentage distribution is illustrated in *Fig.* 2 and a significant difference between the sexes is shown (K–S, D = 0·172, $n_1 = 462$, $n_2 = 492$). There is a female predominance of cancer of the proximal colon which gradually changes to a male predominance of cancer of the rectum.

Unfortunately, the registration system did not allow for the recording of synchronous or metachronous primary tumours.

Stage of disease: The NCR stages large bowel cancer according to the following definitions:

Stage 1. Localized within the organ of origin.

Stage 2. Spread throughout the wall of the organ of origin but not into adjacent tissue (nodes not involved).

Stage 3. Regional spread with lymph node involvement.

Stage 4. Involving other organs or with distant metastases.

It will be appreciated that stages 1, 2 and 3 are similar to Dukes' stages A, B and C for rectal cancer (Dukes, 1932), but unfortunately are not defined in such a precise way.

Of the 992 patients, 951 were staged (i.e. 96 per cent). Most were staged pathologically, but some not having either surgical treatment or a post-mortem were staged clinically. There were 8·9 per cent with stage 1 lesions, 29·6 per cent with stage 2, 35·2 per cent with stage 3 and 26·3 per cent with stage 4 lesions. This means that over 60 per cent of the patients had lymph node metastases or advanced lesions at the time of diagnosis or treatment. There appeared to be a tendency for colonic tumours to be more advanced than rectal ones, but this did not achieve statistical significance (MWU, $Z = 1·95$).

Management

The generally accepted primary treatment for large bowel cancer is surgical excision. The surgeons in Canterbury adhere to this policy though they vary in such matters as the extent of associated lymphadenectomy. During the 5 years under study, there were 18 consultant general surgeons who undertook the bulk of the surgery, with registrars doing a smaller amount. Most of these operations were performed in 4 public hospitals (Christchurch, Princess Margaret, Ashburton and Timaru Hospitals) with a lesser number in 3 private hospitals (approximately 7 per cent in 1974).

Type of management: The types of management have been broadly classified as curative (when all known tumour was excised), palliative (when suspected or proved growth remained *in situ*) or no specific treatment. Of the 992 patients, 980 were classified in this way. Only 65 per cent of these were able to have potentially curative resections. Sixteen per cent had palliative procedures, most of which involved removal of the primary tumour and it is noteworthy that no bypass procedures or colostomies alone were recorded in the 5-year period. The overall resection rate was 79 per cent.

In *Tables II* and *III* the types of management for cancer of the colon and cancer of the rectum are given. The 38 patients with cancer of the large

intestine (site unspecified) were managed in the following ways: curative treatment, 5; palliative treatment, 6; no treatment, 21; not known, 6. A total of 183 patients (i.e. 18·5 per cent of the whole group) received no specific treatment. The main reasons for this were: extent of disease (60 per cent), advanced age or poor general condition (27 per cent) and refusal of treatment (5 per cent).

Early mortality: Hospital or operative mortality was not recorded. However, knowing the number of people who died in the month of treatment and in the month following, we derived the upper and lower limits of the 1-month mortality rate. The mean of these two figures is our estimate of 1-month mortality. Arguably, this is a reasonable guide to hospital mortality. The 1-month mortality rate of the whole group of 992 patients was 12·8 (9·3–16·2) per cent. In the case of curative treatment the figures are 5·1 (3·4–6·7) per cent, for palliative treatment 11·7 (6·3–17·1) per cent and for no treatment 40·2 (31·7–48·6) per cent.

Survival

The survival data are accurate to the end of December 1975, because it takes up to 2 years for mortality returns to be received. Therefore, only patients treated in 1970 have been followed for 5 years. However, by using the life-table method we can give estimates of 5-year survival based on information about all the patients.

The crude 5-year survival rate for the whole group of 992 people is 32·7 per cent (s.e. mean = 1·9 per cent) and the relative survival rate is 42·8 per cent. In *Fig*. 3 the estimated crude survival curve is shown and compared with the survival curve of the general population with the same age–sex structure (*New Zealand Life-tables 1970–72*, 1975).

Factors influencing survival: The estimated survival by category of management is shown graphically in *Fig*. 4. Approximately half the patients having curative resections can be expected to survive for 5 years; the crude survival rate is 48·4 per cent (s.e. mean = 2·5 per cent) and the relative survival rate is 62·4 per cent. It is noteworthy that survival after curative resections was better for rectal cancer than for colonic cancer (rectum—crude 56·4 per cent, s.e. mean = 4·0 per cent, and relative 70·8 per cent; colon—crude 43·5 per cent, s.e. mean = 3·2 per cent, and relative 57·3 per cent). This difference was statistically significant (LRT, $\chi^2 = 6{\cdot}69$, d.f. = 1). We cannot explain this on the basis of differences in staging or age structure.

The 5-year survival rates for those undergoing palliative treatment or no treatment are not yet available. However, the crude 4-year rates are: palliative treatment 8·9 per cent (s.e. mean = 2·6 per cent); no treatment 2·8 per cent (s.e. mean = 1·3 per cent).

In previous papers good correlation has been demonstrated between survival and the extent of disease at the time of treatment (Bussey and Morson, 1963; Gill and Morris, 1978). The estimated survival curves relating to stage of disease for those patients who received either curative or palliative treatment are given in *Fig*. 5. The crude 5-year rates are: stage 1, 68·4 per cent (s.e. mean = 6·5 per cent); stage 2, 58·1 per cent (s.e. mean = 3·6 per cent); stage 3, 32·0 per cent (s.e. mean = 3·8 per cent); stage 4, not available,

n.g., Not given.

the 4 year-rate was 8·6 per cent (s.e. mean = 2·6 per cent).

It is planned to look in more detail at these and other factors that may influence survival when all patients have 'been in' for 5 years, at which time more accurate 5-year figures can be given and reasonable estimates of 10-year survival made.

Discussion

There were, unfortunately, a number of defects in the recording system used when these patients were registered. For example, there is no information about metachronous or synchronous tumours, the mode of presentation is not available and the classification of treatments is not particularly satisfactory. A new and more detailed method of registration, based on World Health Organization recommendations (*International Classification of Diseases for Oncology*, 1976) came into operation at the beginning of 1978. In addition, the NCR is becoming fully computerized. These changes should improve the scope and quality of available information in the future. However, in spite of these limitations, the series illustrates some important points.

First, the high incidence of large bowel cancer in New Zealand is well demonstrated. The rates for rectal cancer are similar in the several populations given in *Table I*, but there seems to be a substantially higher incidence of colonic cancer in New Zealand and North America than in Europe. This may be related to the finding in Connecticut, USA, that the incidence of tumours proximal to the rectosigmoid junction has increased in the past 30 years (Snyder et al., 1977). Another interesting finding is the difference in site incidence between the sexes. There is a higher incidence of proximal colonic cancer in women than in men and this gradually changes distally until, in the rectum, there is a higher incidence of cancer in men than women. An important consequence of this finding is that any theory about the cause of large bowel cancer should explain the substantial sex differences.

The series is similar to other population-based studies in that over 60 per cent of the patients had advanced disease or lymph node metastases at the time of diagnosis or primary treatment. Partly because of this, only 65 per cent were able to have surgery intended to cure them and the overall survival rates are poor. In *Table IV* we have compared some results recently reported from regions, hospitals or individual surgeons. The proportions of patients classified according to type of treatment are given, because such definitions tend to be more uniform than those for pathological staging systems. In any case, they reflect the extent of disease at the time of treatment. It can be appreciated from the Table that if suitable corrections were made for the differing compositions of the series, the survival figures might be very similar.

The point is better illustrated in *Table V*. Curative resections for cancers of the rectum at two specialized centres and in the Canterbury series are compared. Again, if one corrected for differences in staging and operative mortality, the 5-year survival figures would be almost identical. This suggests that the good results reported by special units largely depend on the spectrum of their practice.

In reviewing the literature on this subject, one has been disadvantaged by the lack of uniformity in presentation of results, especially of survival figures. This makes comparisons difficult. It is clear that some authors are less than completely frank about their results; for example, in one paper the only 5-year survival rate given was a *relative* one for the *survivors* of *curative* operations. Not surprisingly, it was over 70 per cent. We suggest that in future both crude and relative rates be given together, that operative mortality be included in these and that overall survival always be given as well as that of particular subgroups. In this way we will not lose sight of the generally unsatisfactory results of treatment.

Acknowledgements

We thank our surgical colleagues in Christchurch, Timaru and Ashburton, for it is their work that we are reporting in this paper. We are indebted to Mr Frank Foster, Chief Health Statistician for New Zealand, and Mr J. Fraser and Miss J. Auld of the National Cancer Registry for access to the basic data and for critical suggestions about this paper. Dr A. McKinnon, Computer Scientist at the Christchurch Clinical School, also provided much help. The study was funded by the Robert McLelland Trust.

Angiodysplasia as a cause of colonic bleeding in the elderly

H. BOGOKOWSKY, S. SLUTZKI AND H. ALON*

SUMMARY

Angiodysplasia is being recognized as a major causal factor of colonic haemorrhage in the elderly. Superior mesenteric arteriography in an 86-year-old lady with recurrent haemorrhage revealed the lesion. Confirmation of the diagnosis was made possible by the injection of contrast material into the blood vessels of the removed intestine and subsequent histological examination.

ANGIODYSPLASIA in the right colon has, in recent times, become recognized as one of the most important causal factors of haemorrhage from the large bowel in the elderly. These vascular malformations of the digestive system are difficult to detect either by endoscopy or by barium meal examination. Selective arteriography of the superior mesenteric artery is the most valuable diagnostic tool.

Case report

An 86-year-old woman, known to be suffering from aortic stenosis and mild heart failure, was admitted with rectal bleeding in October 1975. Endoscopy and barium meal examinations failed to reveal the source of the bleeding. After blood transfusion the bleeding abated.

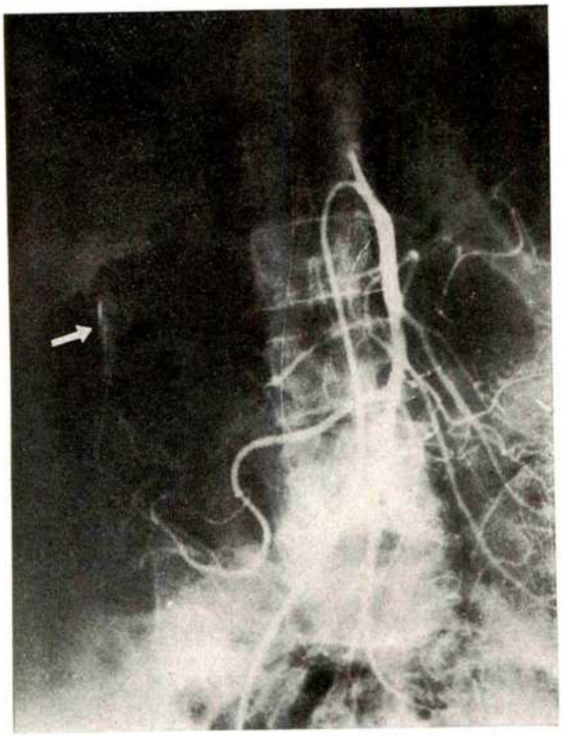

Fig. 1. Superior mesenteric arteriography showing early venous phase, with leak of contrast material into the lumen of the ascending colon (arrow).

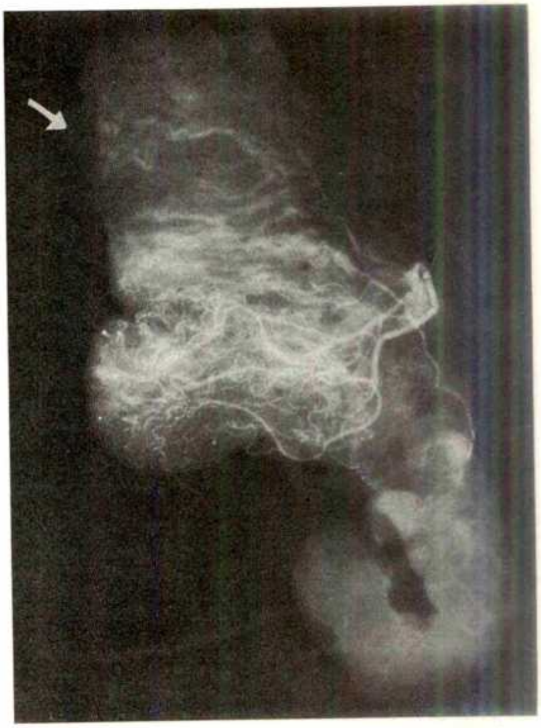

Fig. 2. Radiograph of the excised specimen showing the arteries, which are injected with radio-opaque material. The arrow shows the area of angiodysplasia from which histological sections were taken.

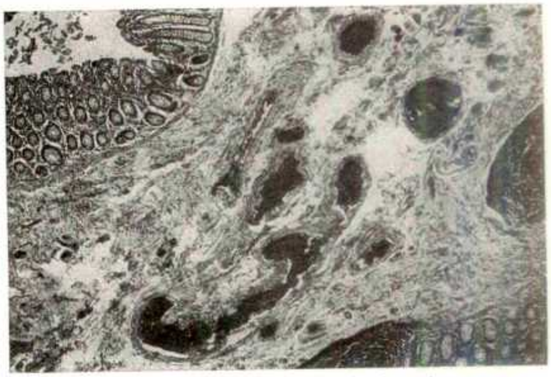

Fig. 3. Showing dilated vascular lakes in the submucosa, which are characteristic of angiodysplasia. (× 80).

* Department of Surgery, Asaf Harofe Government Hospital, Zerifin, and the Sackler School of Medicine, Tel-Aviv University, Israel.

In February 1977 the patient was readmitted with severe rectal bleeding, and at this time a polyp was found in the sigmoid colon. It was suspected that this was the cause of the bleeding and a sigmoid colectomy was performed.

Two months later the patient was again admitted with recurrent rectal bleeding. At this time selective arteriography of the superior mesenteric artery revealed a leak of contrast material into the lumen of the ascending colon (*Fig.* 1). The bleeding persisted and a right hemicolectomy was performed. Her postoperative course was uneventful and she was reviewed in the follow-up clinic. At her last visit in July 1978 the patient, now in her eighty-ninth year, was free of any further rectal bleeding.

The diagnosis of angiodysplasia was confirmed by injection of barium diluted with Gastrografin into the blood vessels of the resected colon (*Fig.* 2). Arteriovenous malformations were demonstrated, and microscopic examination showed clusters of dilated blood vessels, which took the form of contrast-filled lakes in the submucosa (*Fig.* 3).

Discussion

It has recently become apparent that angiodysplasias or vascular ectasias are responsible for colonic bleeding as frequently as diverticulosis in the elderly (Cooperman and Kelly, 1972; Margulis and Castelman, 1974; Crichlow et al., 1975; Moore et al., 1976; Boley et al., 1977; Hagihara et al., 1977; Marx et al., 1977; Welch et al., 1978).

Margulis et al. in 1960 first demonstrated by arteriography the extravasation of contrast material into the intestinal lumen during active bleeding. Baum et al. (1972) initially described the pathological features of this disease, which have been further elucidated by Boley et al. (1977). The lesions are arteriovenous fistulas or aneurysms that penetrate the muscularis mucosa and are seen as submucosal vascular lakes. The aetiology of these lesions is not certain but several theories exist.

Heyde (1958) found a statistical association of aortic stenosis and gastrointestinal bleeding and Williams (1961) surveyed 1443 cases of gastrointestinal bleeding at the Massachusetts General Hospital and found that there was a 25·5 per cent relationship with aortic stenosis. However, Marx et al. (1977) discounted this relationship.

Baum et al. (1975) attributed these vascular malformations to a submucosal leak occurring during periods of hypotension.

Boley et al. (1977) have suggested that the lesions may be caused by long term, low grade obstruction of the submucosal venules, especially where they pierce the muscular layers of the bowel. This results in retrograde dilatation of these venules, and when there is finally loss of the function of the precapillary sphincters, small arteriovenous fistulas are produced. Diagnosis is made by selective arteriography. During active bleeding there may be extravasation of contrast medium into the lumen of the bowel. This, however, occurs only if the bleeding is brisk. Pathognomonic signs are the accumulation of contrast material in vascular tufts during the capillary phase. The venous phase shows early filling of large veins, indicating arteriovenous fistulas. The arterial phase is normal.

If the lesion is detected, a right hemicolectomy is performed, since the natural history of these lesions is one of recurrent bleeding. Welch et al. (1978) report that in 12 per cent of patients who underwent only a segmental colectomy, rebleeding occurred. Boley et al. (1977) note that rebleeding is rare after right hemicolectomy.

The identification of the lesions by the pathologist may be difficult unless the 'coral head' appearance of advanced angiodysplasia is seen (Boley et al., 1977). In order to localize the lesions, the vessels of the excised intestine were first injected with a mixture of barium in Gastrografin. The specimen was then X-rayed, revealing the area of angiodysplasia. In this way it was possible to localize the lesion and take accurate specimens for histological examination.

Angiodysplasia is not known to be a major cause of colonic bleeding in the elderly. In these patients the use of arteriography and the performance of a right hemicolectomy will greatly improve the prognosis.

Extra-intracranial revascularization

J. S. P. LUMLEY*

SUMMARY

Twenty-four extra-intracranial revascularization procedures were undertaken in 23 patients with occlusion of the ipsilateral internal carotid artery. The superficial temporal artery was anastomosed to a cortical branch of the middle cerebral artery in 23 cases and a vein graft inserted between the external carotid artery and the cortical vessel in 1, a microsurgical technique being used.

Twenty-one patients were suffering from transient ischaemic attacks (TIAs) and 2 had developing strokes. Nineteen patients had radiologically demonstrated bilateral disease of the carotid vessels, 9 having undergone contralateral carotid artery surgery before the intracranial procedure.

No improvement was noted in the 2 patients with developing strokes; one patient developed a stroke contralateral to the intracranial procedure 24 h postoperatively, this being accompanied by occlusion of the anastomoses, and one patient had progression of the stroke syndrome following occlusion of the intracranial vein graft. All other patients have shown a reduction or abolition of TIAs over a follow-up period of 24 months.

These findings suggest that intracranial revascularization is of value in patients with total internal carotid artery occlusion and continuing TIAs.

THE role of reconstructive surgery in the extracranial portion of the carotid system for patients with stroke syndromes is now well established (Taylor and Lumley, 1977a, b). The usual pathology is a stenotic lesion of the common carotid bifurcation and the presenting symptoms are those of recurrent motor or sensory TIAs affecting the appropriate hemisphere or amaurosis fugax. In a small proportion of patients the internal carotid artery becomes totally occluded and in this situation the chances of restoring patency are higher with early operation but so are the risks of haemorrhage into a recent infarct (Bruetman et al., 1963; Blaisdell et al., 1969).

Some patients survive a total occlusion of the internal carotid artery without the development of a major stroke but later suffer from TIAs appropriate to the ischaemic hemisphere. The long term prognosis is poor in this group, Ziegler and Hassanein (1973) reporting a 45 per cent incidence of major strokes within a 3-year period. In 1968, Donaghy and Yasargil gave a preliminary report of a new technique of revascularizing the intracerebral vessels by means of a superficial temporal to middle cerebral artery (ST–MCA) bypass using microsurgical techniques. Lougheed et al. (1971) studied the possibilities of grafting on to the intracranial portion of the internal carotid artery, but surgeons have generally favoured the originally described ST–MCA anastomoses. A number of reports have now appeared in the overseas literature as to the efficacy of this procedure for patients with the stroke syndrome (Yasargil et al., 1970; Reichman et al., 1972; Austin et al., 1974; Yonekawa and Yasargil, 1976; Chater 1976a, b; Holbach et al., 1976; Sundt et al., 1976) and more recently reports have been published from British centres (Lumley, 1976, 1978; Bannister, 1977). This paper discusses the first 24 procedures undertaken by the Surgical Professorial Unit at St Bartholomew's Hospital, the longest follow-up being 24 months.

Patients and methods

The presenting symptoms, angiographic findings and operative details of the 23 patients are summarized in *Table I*. Referrals were initially from neurologists in 15 cases, ophthalmic surgeons in 2 and peripheral vascular clinics in 3 cases.

Twenty-one of the 23 patients were male and all were right-handed; their average age was 59·6 years and the average length of history was 19·3 months. The term 'TIA' in *Table I* has been used to indicate all reversible neurological episodes, which were of the prolonged variety in only 2 patients. Visual episodes reported in the Table are amaurosis fugax unless stated to the contrary. Dysphasia is not subdivided. As psychological tests with a Halstead–Reitan battery were only performed on some of the patients, the reported memory and mental changes represent description by the patient or close relatives. The number of neurological episodes was 3 or less in 7 patients and in excess of 20 in 6 patients.

The blood pressure readings presented are from the right upper limb at the time of the intracranial procedure; there was no marked variation from left arm pressures in any patient. Angiographic assessment included bilateral carotid arteriography by direct stab or selective catheterization techniques. Angiographic findings were those of arteriosclerosis in all patients, this diagnosis being confirmed histologically in the 11 patients undergoing carotid artery surgery in the neck.

In *Cases* 12, 17 and 21, the internal carotid artery was occluded distal to its ophthalmic branch. In *Cases* 2, 5 and 11 the internal carotid artery on the side of the intracerebral anastomosis was not occluded at the time of arteriographic assessment. In *Cases* 2 and 11, however, there was minimal backflow from the internal carotid at the time of initial exploration and in view of radiologically demonstrated thrombus in the carotid syphon in *Case* 2 and severe distal stenosis in *Case* 11, the internal carotid artery was disconnected and the origin of the external carotid artery rebored and refashioned in each case. In *Case* 5, although the internal carotid artery was patent at the time of angiography, it had occluded by the time of exploration in the neck.

The first intracranial procedure was undertaken on 18 April 1976, the last being performed on 21 April 1978.

Surgical technique

The aim of the operative procedure is to provide an additional arterial blood supply to the cerebral hemisphere beyond an occluded internal carotid artery. In the absence of serious neurological defects the cortical branches of the middle cerebral artery are usually patent and one or more of these branches are used to introduce a new blood supply. The superficial temporal artery over the temporal region is of equivalent size to a cortical vessel. If the blood flow in this artery is unimpaired it is divided and the proximal end anastomosed end to side on to the cortical vessel using microsurgical techniques. In 9 patients a frontoparietal skin flap was raised, the superficial temporal artery being dissected on a fascial pedicle from the deep surface of the flap. In the other cases the artery was mobilized through a skin incision over it.

* Cases 10 and 15 are the same patient undergoing two procedures.

The bony approach was centred 6 cm superior and 1 cm posterior to the external auditory meatus, a separate vertical skin incision being used when a flap was not raised. Initially a craniotomy was used, but a craniectomy was subsequently made, a single burr hole being enlarged as necessary.

The dura mater was incised in stellate fashion, and an adjacent parietal or angular branch of the middle cerebral artery was mobilized for the anastomosis. The anastomosis was fashioned with interrupted 10/0 monofilament nylon using a Zeiss operating microscope. Systemic heparin was used in *Case* 5 where an external carotid artery to middle artery vein bypass was being inserted. Prophylactic antibiotics were administered for 1 week and phenobarbitone was prescribed as an anticonvulsant over the operative period and for 3 weeks postoperatively. The latter medication was reintroduced 4 months later in *Case* 1 when this patient had three focal epileptiform attacks. Dipyridamol and aspirin were administered to the later patients in the series.

Results

Postoperative progress is summarized in *Table I*. Patency of the anastomosis was assessed by digital and Doppler examinations of the superficial temporal artery. The vein graft in *Case* 5 failed after 3 months and the ST–MCA bypass failed in *Case* 20 (it is not known whether this occurred immediately before or after his stroke). A weak Doppler signal is present to near the burr hole in 3 cases and patency is questionable, but the remainder are considered patent on Doppler and clinical testing. Cerebral blood flow was also studied by different isotope techniques at three centres. In *Case* 1 postoperative angiography of the anastomosis was undertaken at 3 weeks and 12 months (*Figs*. 1, 2), but routine postoperative angiography has not been performed.

There were no recurrent postoperative motor TIAs recorded contralateral to the intracerebral anastomosis, however established weakness on this side was not markedly altered, of particular note being the persistent paresis in the 2 patients with developing strokes (*Cases* 13 and 7). *Case* 17 developed a terminal stroke ipsilateral to the ST–MCA anastomosis 4 weeks after the procedure. *Case* 20 was operated upon as an emergency after two episodes of dense but transient motor paresis, but the operation did not prevent the onset of a dense paresis 24 h later. Mental improvement in *Cases* 6, 9 and 10 (15), while not recorded quantitatively, was subjectively marked as assessed by patients and relatives. *Cases* 1 and 9, although of employable age, have not returned to full employment; both have been under psychiatric care for long term alcoholic problems.

Discussion

The incapacity and other consequences of stroke on a patient and those close to him make the search for means of prevention an important medical priority. Initial progress in the field was stimulated by the realization that major strokes were often preceded by TIAs and the disease process was often in the surgically accessible extracranial arteries (Eastcott et al., 1954). Treatment of patients with an occluded internal carotid artery in its inaccessible portion by ST–MCA bypass was pioneered by Donaghy and Yasargil (Donaghy, 1967; Yasargil, 1969a, b).

All the patients in the present series were suffering from arteriosclerosis; this predominance has also been present in other series although the use of extra–intracranial bypass has been advocated in a variety of other diseases (Reichman, 1975; Chater and Popp, 1976; Sundt et al., 1976; Yonekawa and Yasargil, 1976). All except 2 of the patients had motor, sensory or visual TIAs or persistent neurological symptoms related to an occluded internal carotid artery. The

marked reduction of TIAs is encouraging. Yonekawa and Yasargil (1976) reported a 75 per cent relief of symptoms while Chater and Popp (1976) reported a 92 per cent relief from or substantial reduction of TIAs.

The most disappointing result in the present series was that in *Case* 20, where it was hoped that recent motor TIAs of increasing severity could be abolished. It is not known whether the occlusion of the ST–MCA bypass in this patient preceded or followed the stroke he developed 24 h postoperatively, or indeed whether the operation precipitated the event. The bypass operation undertaken in 2 patients with developing strokes did nothing to reverse the established neurological deficit, although it could be argued that there was no further contralateral deterioration in either case. One of these patients suffered an ipsilateral progressive stroke; this was the only death in the series. These results in the patient with developing stroke do not encourage the use of cerebral revascularization in this particular group. Chater and Popp (1976) did note an improvement in 5 patients who presented with progressive deterioration of the neurological status but no improvement in patients with moderate or severe persistent neurological deficits.

The absence of late strokes in the group is encouraging but has to be judged in the light of the limited follow-up period. Chater (1976b), on analysis of his follow-up, showed that there was a 3 per cent postoperative incidence of strokes related to the area supplied by the bypass and in one of these 3 cases the stroke accompanied occlusion of the bypass. The overall incidence of strokes in his series was 7 per cent, this including strokes referable to the non-operated hemisphere. Chater estimated from the results of Whisnant et al. (1973) that there would have been a 22 per cent incidence of strokes in the same group of patients if they had been treated conservatively. Operative mortality in Chater's group was 1·4 per cent.

The mental improvement seen in the present series is difficult to interpret in the absence of objective testing, although striking to local observers. These findings are consistent with those of Perry et al. (1975) and of Ferguson and Peerless (1976), who advocated the use of intracranial revascularization in patients with dementia related to widespread cerebrovascular disease.

The arteriographic techniques in the present series were partly dependent on the preference of the referring physician. It is essential to obtain adequate information on the intracranial circulation in patients presenting with TIAs in order to exclude the presence of tumours, angiomas and aneurysms as well as to assess the extent of the arterial disease. This information can be obtained by direct carotid puncture or by selected injections from the aortic arch. Arch aortography is indicated when vertebrobasilar insufficiency or an associated subclavian steal are being investigated. Selective carotid arteriograms, however, require more elaborate apparatus, the use of larger volumes of contrast media and take longer to perform than direct stab techniques.

The widespread nature of the arterial disease seen in this series is also reflected in other reports. Yonekawa and Yasargil (1976) reported a 37 per cent incidence of bilateral internal carotid artery occlusion while Sundt et al. (1976) described a 15 per cent incidence of bilateral disease.

When considering the surgical techniques, some surgeons raise a skin flap and a branch of the superficial temporal artery is dissected from its deep surface (Yasargil et al., 1970; Chater and Peters, 1976; Sundt et al., 1976; Yonekawa and Yasargil, 1976). The incidence of flap necrosis reported after this method ranged from 2 to 10 per cent (Chater, 1976a; Sundt et al., 1976). One patient in the present series had delayed healing of a scalp flap. Primary union was obtained in all cases where the superficial temporal artery was mobilized by an incision directly over it. In no case in the present series was it necessary to use the occipital artery for bypass. In the one case requiring a vein graft the occipital and superficial temporal artery were both inadequate. The value of vein grafts in this area still requires careful study.

Although a 1-cm burr hole is large enough to undertake an ST–MCA anastomosis, as the adequacy of the adjacent cortical arteries cannot be predicted before the dural incision, it is usual to make a 3–5-cm craniectomy. In this series the parietal or angular branch of the middle cerebral artery was used for anastomosis as advocated by Chater and his associates (Chater and Peters, 1976; Chater and Popp, 1976; Chater et al., 1976). The largest available cortical vessel was chosen while avoiding damage to perforating branches. Through a small craniectomy it is often not possible to distinguish the angular branch from parietal branches. Yonekawa and Yasargil (1976) advocated the use of a temporal branch of the middle cerebral complex while Reichman and his associates (Reichman, 1975; Reichman et al., 1972, 1974, 1975), although willing to use any branch of the middle cerebral complex, aimed to place the anastomosis over the area at risk. A rich anastomosis has been reported between the branches of the middle cerebral artery (Feindel, 1970), and temporary occlusion of a cortical vessel does not appear to lead to permanent ischaemic damage. Heparin is ill-advised in neurosurgery, it has not been advocated in intracranial revascularization and, in the one case where it was administered systemically in the present series, continued oozing proved difficult to control and greatly hindered the completion of the anastomosis.

Technical details of microsurgery, such as the degree of magnification, the type of arterial clamp, the method of incising the cortical vessel, the incision and placing of the superficial temporal artery, the use of stents and of dams and the order of stitching, differ considerably between surgeons. The most important factor, however, is that the operator should gain considerable preliminary experience in microvascular surgical techniques in small animal research.

The routine use of anticonvulsants is not universal. Yonekawa and Yasargil (1976) reported an 8 per cent incidence of postoperative fits but they withheld treatment until a fit manifested itself. Antiplatelet drugs such as dipyridamol and aspirin have not been advocated routinely in this field but, from experience in other microvascular techniques and on theoretical grounds, they would appear to be of value.

The determination of the patency of the ST–MCA anastomosis in the early and later postoperative period is not as easy to assess as might be supposed. If one can palpate the superficial temporal artery into the craniectomy, the vessel is probably functioning. At this site, however, it is usually covered by the temporalis muscle and fascia and is difficult to palpate. Presence of a palpable superficial temporal artery in the pre-auricular area may indicate anastomotic patency but may also be related to filling of another branch. The Doppler probe is a useful tool and, where the vessel diameter has been recorded, an estimated superficial temporal artery flow can be obtained by this means (Sundt et al., 1976). Carotid arteriography by selective or carotid stab techniques carries with it a small morbidity and in the initial postoperative phase may fail to demonstrate a patent anastomosis. This is thought to be due to slow flow in the superficial temporal artery, perhaps related to initial oedema and spasm, or possible failure to time exposures correctly. The value of cerebral blood flow measurement using various isotopic techniques is still under investigation in the present series.

A distinct learning curve was reported by Sundt et al. (1976) when assessing graft patency. These authors reported 25 per cent patency in initial studies but 99 per cent patency in more recent procedures. Yonekawa and Yasargil (1976) reported an 85 per cent patency in their series as assessed mainly arteriographically while Chater and Popp (1976) reported a 95 per cent graft patency when assessed by Doppler ultrasound.

Postoperative progress in these patients is smoother than it often is after carotid artery surgery in the neck, where there can be marked instability of blood pressure in the postoperative period (Angell-James and Lumley, 1974).

The results of this series confirm the findings of others, earlier in the field, that extra–intracranial revascularization procedures can carry a low morbidity and mortality even though undertaken in a high risk group of patients. Follow-up in this series shows a marked reduction in TIAs while long term results in the existing literature suggest that the procedure is of value in stroke prevention. It appears that this form of surgery can take its place alongside carotid endarterectomy as a means of prophylaxis in the treatment of the stroke syndrome. Patients with an occluded internal carotid artery and TIAs should be treated by intracerebral revascularization before the development of irreversible neurological deficits. The procedure requires meticulous surgical techniques and adequate training in both microvascular and neurosurgical fields.

Deep vein thrombosis after total hip replacement: a clinical and phlebographic study

ANDERS S. NILLIUS AND GÖRAN NYLANDER*

SUMMARY

Two hundred and forty-seven phlebograms (113 bilateral and 21 unilateral) were performed in 134 patients 10-14 days after total hip replacement. Fifty-eight per cent of the patients were found to have deep vein thrombosis. The patients with DVT were significantly older than patients without DVT, but there was no difference regarding sex, type of hip prosthesis, side of operation or day of mobilization. No difference was found in the duration of operation and anaesthesia, the operative haemorrhage and the amount of bank blood transfused in patients with and without DVT.

Fifty per cent of the thrombi were confined to the calf veins. Ninety-seven per cent of these thrombi were asymptomatic and were as frequent on the operated as on the non-operated side. The remaining 50 per cent of the thrombi engaged the thigh with or without simultaneous calf vein involvement. These thrombi produced symptoms in 23 per cent of the cases and were significantly more common on the operated than on the non-operated side.

It is concluded that DVT after hip replacement can be of two different types: thrombosis caused by stasis and the general effects of trauma and thrombosis caused by local factors involving the thigh veins of the operated leg.

DEEP vein thrombosis (DVT) is a common postoperative complication (Kakkar et al., 1969). The pattern of DVT after hip surgery differs in several respects from that seen in general surgery. The incidence of DVT after hip surgery is considerably higher (Evarts and Feil, 1971; Hampson et al., 1974). Iliofemoral thrombi are common, and thrombi in the thigh often occur isolated from DVT in the calf (Harris et al., 1977). Factors reputed to contribute to the high incidence of thrombi after hip surgery include advanced age, prolonged postoperative bed rest and major trauma to the tissues with activation of the coagulation system (Sevitt and Gallagher, 1961; Walsh et al., 1976). Manipulation of the leg in connection with total hip replacement with intraoperative distortion and occlusion of the femoral vein has also been claimed to be a cause of DVT (Stamatakis et al., 1976).

The aim of the present investigation was to study the location and frequency of various types of postoperative deep vein thrombi and to evaluate the importance of various factors connected with hip operations in the development of postoperative DVT.

Patients and methods

The material consisted of 134 patients with osteoarthritis of the hip who had total hip replacements performed during the period of May 1975 to May 1977. All patients were given dextran 70 (Macrodex 6 per cent in saline, Pharmacia AB, Sweden) as a thromboembolic prophylaxis. Preoperative normovolaemic haemodilution with dextran 70 was performed in 54 patients. This haemodilution was performed as follows. After induction of anaesthesia, but before the operative procedure, haemodilution was performed by replacing blood with dextran to lower the haematocrit to 25-30. The volume of the drained blood was substituted by the same volume of dextran to maintain normovolaemia. The technique of preoperative haemodilution in total hip replacement has been previously described in detail (Ahlberg et al., 1977). The remaining 80 patients were given 500 ml of dextran 70 during the operation (starting after induction of anaesthesia) and on the second postoperative day. Age, sex, type of hip prosthesis and side of operation are presented in *Table I*.

Table I: CLINICAL MATERIAL

Right	80
Left	54
Total	134

For all patients the following variables were recorded: time of operation and anaesthesia; operative haemorrhage, calculated from operative bleeding and from suction drains postoperatively; amount of bank blood transfused during operation and postoperatively; day of mobilization (walking with weight bearing).

All patients had phlebograms performed 10-14 days postoperatively. No special effort was made to diagnose deep vein thrombosis clinically, but patients with symptoms suggestive of DVT were subjected to immediate phlebography. The phlebograms were performed according to a technique described earlier (Brodelius et al., 1971; Nylander, 1971). It can be summarized as follows. The lower leg was examined in a vertical position with horizontal beam direction. Contrast medium (30 ml Isopaque, Amin, Nyegaard) was injected into a dorsal foot vein. Frontal and lateral films were obtained. The deep veins of the knee, thigh and iliofemoral region were examined with the patient in the supine position and vertical beam direction. Another 30 ml of contrast medium were injected into the large saphenous vein at the level of the knee. The contrast medium was distributed to the deep veins through the perforating veins by two tourniquets, one firmly wrapped around the uppermost part of the thigh and the other around the leg below the knee. Frontal views of the iliofemoral veins were obtained before and after releasing the uppermost tourniquet. In a few patients, where the iliofemoral veins were occluded by thrombi, the iliac veins were visualized by injection of 20 ml of contrast medium into a superficial vein in the groin. Bilateral phlebograms were performed in 113 patients and 21 patients were subjected to unilateral phlebography. The results of the phlebograms were grouped according to the following system:

A. Normal.

B. Lower leg DVT (DVT confined to the veins of the lower leg and not extending above the popliteal vein).

C. Lower leg and femoral DVT (lower leg DVT with isolated thrombosis also in the deep veins of the thigh).

---

* Departments of Orthopaedic Surgery and Radiology, Malmö General Hospital (University of Lund), Malmö, Sweden.

D. Femoral DVT (isolated DVT in the thigh).

E. Extensive DVT (total occlusion of the deep veins in the lower limb up to the inguinal region).

The data were compared using the χ^2 test with Yates's correction and the Student's t test.

Results

The results of the phlebograms in all patients are presented in *Fig.* 1. Seventy-eight of the 134 patients included in the study had DVT (58 per cent). Fifty per cent of the thrombi engaged the thigh veins. Thrombi in the thigh without lower leg DVT were found in 10 patients (13 per cent). Most thrombi in the thigh region were isolated from thrombi in the calf (23 out of 39, 59 per cent). The distribution of DVT in relation to age, sex, type of hip prosthesis and side of operation is shown in *Table II.* The distribution of thrombi in bilateral phlebograms (*Fig.* 2) shows that lower leg DVT was as common in the operated leg as in the non-operated leg, whereas involvement of thigh veins was significantly more common in the operated leg ($P<0.05$). Patients with and without DVT, respectively, were compared with regard to age, time of operation, time of anaesthesia, operative haemorrhage, amount of homologous blood transfused and day of mobilization postoperatively. The results are shown in *Table III.* The patients with DVT were significantly older ($P<0.001$). There was no difference in the other variables between patients with and without DVT. Ten patients had DVT with symptoms—clinical DVT—and 2 more patients had clinical symptoms of DVT but the results of phlebography were normal. The patients with clinical DVT are indicated in *Fig.* 1 and *Table II.* All but one of the clinical thrombi occurred in the operated leg. Most clinical thrombi engaged the thigh and 60 per cent of these thrombi were extensive.

Discussion

The incidence of postoperative DVT, among other factors, depends on the diagnostic techniques used. In this study all deep veins, including the muscle veins of the calf, were included and the deep veins were examined up to the confluence with the inferior vena cava. All phlebograms were scrutinized by an experienced radiologist. All thrombi detected, no matter how small, were recorded as DVT. This might explain the high incidence of DVT in these patients despite dextran prophylaxis.

The high incidence of isolated thigh vein thrombi (29 per cent) in this study greatly exceeds the incidence of this type of thrombus in an unselected series of patients with acute leg thrombosis derived from the same urban population (Nylander and Olivecrona, 1976) and also the incidence reported after major general surgery (Bolton and Hoffman, 1975). This clearly indicates the increased risk for this type of thrombus in patients undergoing total hip replacement.

Lower leg thrombi occurred as often in the operated as in the non-operated leg, whereas thigh thrombi were significantly more frequent in the operated leg. This is in agreement with other studies (Hampson et al., 1974; Hume et al., 1976). In the autopsy study of Sevitt and Gallagher (1961) on patients with unilateral fractures of the lower limb, no relationship between thrombosis and the side of injury was established. However, deep vein thrombosis associated with major pulmonary embolism was more frequent in the injured limb in cases with unilateral thrombosis.

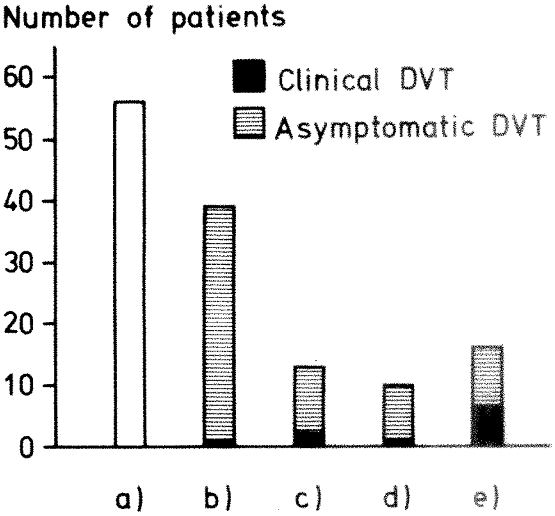

Fig. 1. Results of phlebograms: (a) normal; (b) lower leg DVT; (c) lower leg and femoral DVT; (d) isolated femoral DVT; (e) extensive DVT.

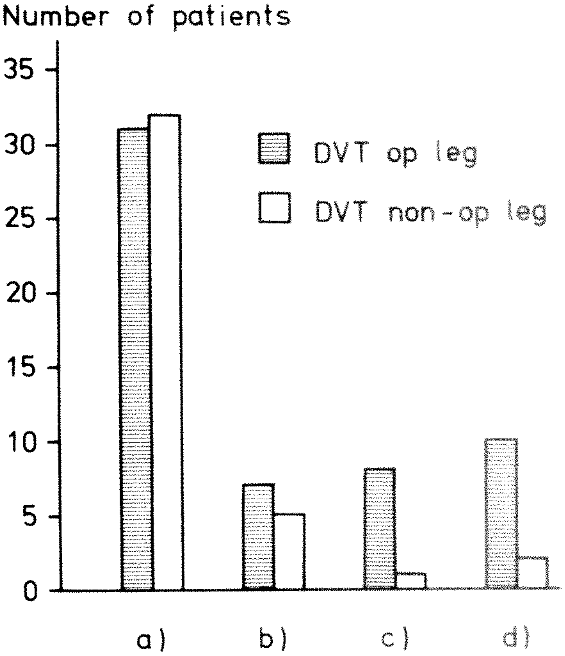

Fig. 2. Distribution of DVT in bilateral phlebograms: (a) lower leg DVT; (b) lower leg and femoral DVT; (c) isolated femoral DVT; (d) extensive DVT.

Clinical symptoms were more common in patients with thigh DVT. Even in extensive deep vein thrombosis, however, only one-third of the patients had clinical symptoms. The high percentage of asymptomatic thrombi in the thigh might explain why most fatal emboli after hip surgery occur without previous signs and symptoms of DVT (Johnson et al., 1976).

In the literature, opinions on the site of origin of venous thrombosis differ. Autopsy studies (McLaughlin and Paterson, 1951; Sevitt and

Transfusion of homologous blood (l)	$1{\cdot}634 \pm 0{\cdot}852$	$1{\cdot}382 \pm 0{\cdot}891$	n.s.

Gallagher, 1961) establish that thrombi can start at multiple sites and that the iliofemoral region is as common as, and perhaps more important than, the calf as a site of DVT. Studies with the ^{125}I-fibrinogen uptake method and the Doppler ultrasound technique have shown that the majority of postoperative thrombi start in the calf veins and that femoral thrombi form by propagation from the calf (Kakkar et al., 1969; Bolton and Hoffman, 1975). The diverging results might be explained partly by technical difficulties in necropsy studies and by the insensitivity of the ^{125}I-fibrinogen method in diagnosing iliofemoral thrombi (Harris et al., 1975). An additional explanation is the time at which the investigations were performed. The ^{125}I-fibrinogen test has mainly been performed in the first 7–10 postoperative days while autopsy studies have been performed in a selected group of patients in the third week. The present study shows that the majority of femoral vein thrombi after total hip replacement are formed in the thigh. Since extensive thrombi in the leg showed the same distribution as isolated femoral thrombi (with the majority being formed in the operated leg), it might be asked whether these thrombi are formed by propagation peripherally from an isolated thrombus in the thigh. In favour of this view are the observations by Hume et al. (1976) that thrombi detected late postoperatively were more extensive. As the patients were monitored by the ^{125}I-fibrinogen method these thrombi would have been detected earlier if they had started in the calf. Thrombi originating from the large veins of the thigh might exist for a long time before occluding the vein completely and causing clinical symptoms. This agrees with the observation that clinical DVT after total hip replacement is often diagnosed 2–3 weeks after operation (Charnley, 1972).

Ambulatory calf volume plethysmography in the assessment of venous insufficiency*

J. FERNANDES E FERNANDES, J. HORNER, T. NEEDHAM AND A. NICOLAIDES†

SUMMARY

Ambulatory calf volume plethysmography has been used to study venous insufficiency in 50 lower limbs. The results demonstrate that it is possible to determine the presence of venous insufficiency and differentiate between normal limbs, limbs with superficial venous insufficiency only, limbs with deep venous insufficiency and limbs with deep venous insufficiency and occlusion by determining the ambulatory volume change and maximum venous outflow or venous volume.

VENOUS insufficiency can be assessed objectively by the measurement of ambulatory venous pressure (Pollack et al., 1949; De Camp et al., 1951; Lewis et al., 1973; Kriessman, 1974). However, this is an invasive technique not suitable for the routine screening of a large number of patients. In the past, venous occlusion plethysmography has been used mainly to establish the patency of deep veins (Dahn and Erikson, 1968; Hallbook and Gothlin, 1971) or to determine the competence of deep venous valves (Bygdeman et al., 1971; Barnes et al., 1972). Recently, it has been suggested that the procedure may be used in the diagnosis of valvular incompetence of both superficial and deep veins (Barnes et al., 1975; Holm, 1976), or to identify in patients with varicose veins segments of normal superficial veins to be preserved during surgical treatment (Holm et al., 1974).

The purpose of the present study was to determine whether ambulatory calf volume plethysmography, which is non-invasive, could distinguish between normal limbs, limbs with superficial valvular incompetence only, limbs with deep valvular incompetence and limbs with deep valvular incompetence and occlusion. In addition, we wanted to develop a test that was not only qualitative but would provide a quantitative measure of the severity of venous incompetence as determined by venous pressure. A non-invasive test that has achieved this had not previously been reported.

Patients and methods

Doppler ultrasound

Directional Doppler ultrasound (Parks, Model 806) was used to determine the presence of reflux at the saphenofemoral and saphenopopliteal junctions and in the popliteal vein. The patients were examined standing. The probe was positioned over the femoral vein at the groin. This position was determined by first localizing the femoral artery and then moving the probe medially until the typical venous flow was heard on manual compression of the thigh. The probe was adjusted so that the maximum audible signal was obtained. The changes on respiration, on Valsalva manoeuvre and on manual calf compression and release were noted. Reflux at the saphenofemoral junction was diagnosed if there was retrograde flow during the Valsalva manoeuvre and on release of calf compression, provided this reflux was abolished by compression of the long saphenous vein at mid-thigh level. The probe was then placed behind the knee, which was slightly flexed, while the patient's weight was on the opposite limb. The position of the probe was adjusted so that the signal from the popliteal artery was audible in addition to the signal from the popliteal vein on calf compression. On release of calf compression, the presence of retrograde flow which was not abolished by digital compression of the short saphenous vein, indicated incompetence of the popliteal valves. Retrograde flow on calf release which was abolished by digital compression of the short saphenous vein indicated reflux at the saphenopopliteal junction.

Ambulatory venous pressure

The ambulatory venous pressure was determined in all limbs. A 21G (bore 20G) 'butterfly' needle was inserted into a vein on the dorsum of the foot and was connected through an Akers transducer (model 840) and a BAP 001 amplifier to a potentiometric pen recorder (J. and J. Instruments, model CR 55amK2).

Venous pressure was measured with the patient standing still and then doing a tip-toe exercise for 20 s at a rate of one heel raising movement per second. This was repeated once after inflating a 2·5-cm pneumatic cuff at the ankle to a pressure of 140 mmHg and a second time after inflating a 2·5-cm pneumatic cuff at the thigh to a pressure of 180 mmHg. Venographic studies have demonstrated that the above pressures will allow occlusion of the superficial veins only, because of the small width of these cuffs (Nicolaides et al., 1971).

Ascending venography

Ascending venography was done in all limbs, except in the 15 normal limbs, in order to determine the presence or absence of deep venous occlusion (Craig, 1977).

Ambulatory calf volume plethysmography

Ambulatory calf volume plethysmography was done in all limbs, using a mercury-in-Silastic strain-gauge plethysmograph (Whitney, 1953) (Model EC-2 supplied by D. E. Hokanson) connected to a pen recorder (Mingograf 34). Two channels were used so that both limbs could be studied simultaneously. The strain-gauge was placed around the thickest part of the calf. The maximum venous outflow (MVO) was first determined with the patient supine and the legs elevated 10° to the horizontal by applying conical cuffs 25 cm wide to the thighs inflated at 60 mmHg for 2 min and then suddenly released. The venous volume (VV), which is the maximum increase in the calf volume, and the maximum venous outflow were calculated from the recordings of the calf volume during the period of occlusion and from the slope of the emptying curve during the first second after release of the thigh cuff (*Fig. 1a*). The coefficient of variation of the determinations of the MVO and VV was less than 6 per cent; this was obtained by repeated measurements in 6 limbs of 3 normal volunteers on 5 consecutive days. The MVO was expressed in ml per 100 ml of tissue per minute (Hallbook and Gothlin, 1971) and the VV in ml per 100 ml of tissue (Dahn and Erikson, 1968). Subsequently, the patient was asked to stand and repeatedly to raise himself on his toes (tip-toeing) at the rate of one movement per second for a period of 20 s. The ambulatory volume change (AVC), which was the maximum volume change during exercise, and the refilling time (t) (Holm, 1976) after exercise were obtained (*Fig. 1b*). The AVC was expressed in ml per 100 ml of tissue and t in seconds. The exercise was repeated with a cuff 2·5 cm wide just below the knee at 100 mmHg, which occluded the superficial veins.

Patients

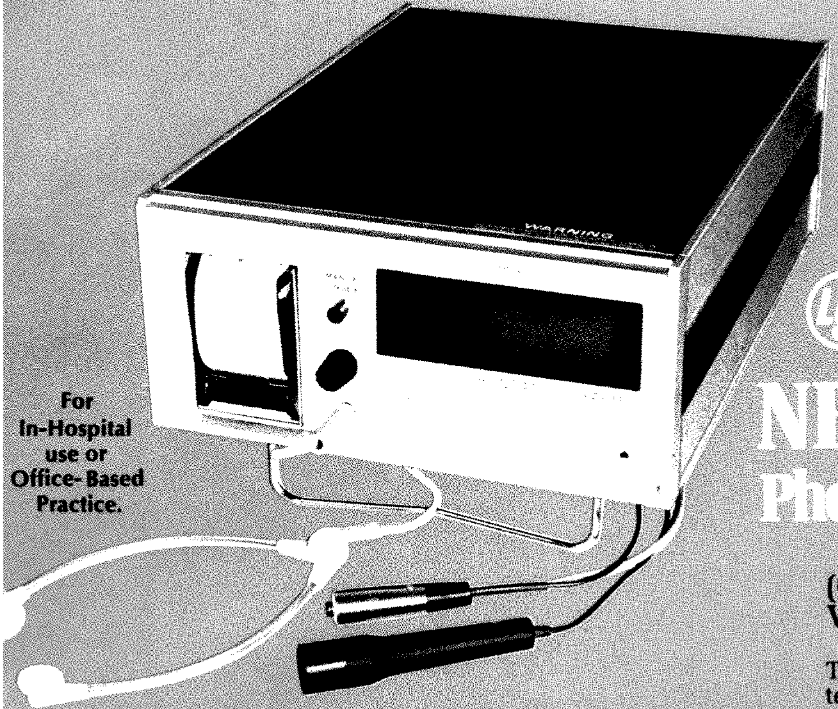
Fifty limbs of 27 subjects (11 male and 16 female) have been studied. The limbs were classified into the following four groups according to the criteria stated below.

Normal: Fifteen limbs were classified as normal because Doppler ultrasound did not demonstrate any reflux and the ambulatory venous pressure was less than 35 mmHg.

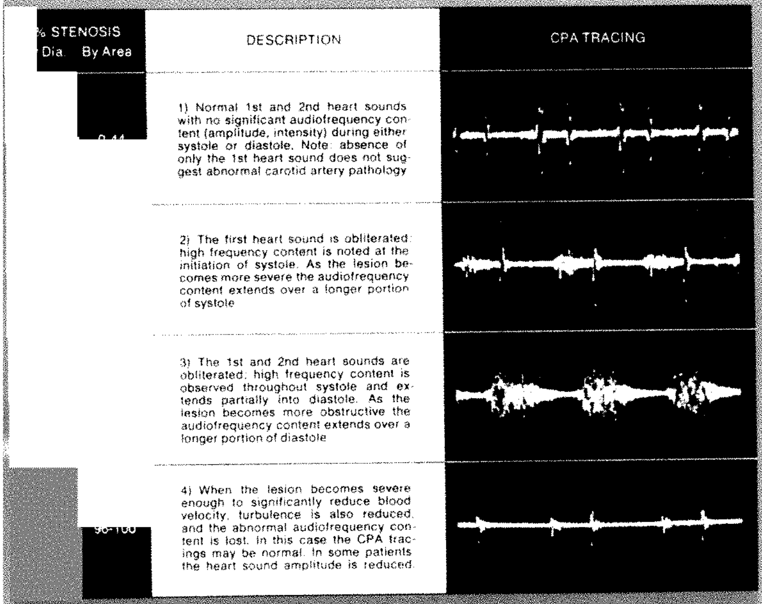
Superficial venous incompetence with competent valves in the deep veins (SVI): Fourteen limbs were included in this group because Doppler ultrasound demonstrated reflux at the saphenofemoral or saphenopopliteal junctions, but no popliteal reflux. The ambulatory venous pressure became less than 33 mmHg only by applying the venous cuffs during tip-toeing.

NEW Recording Phonoangiograph

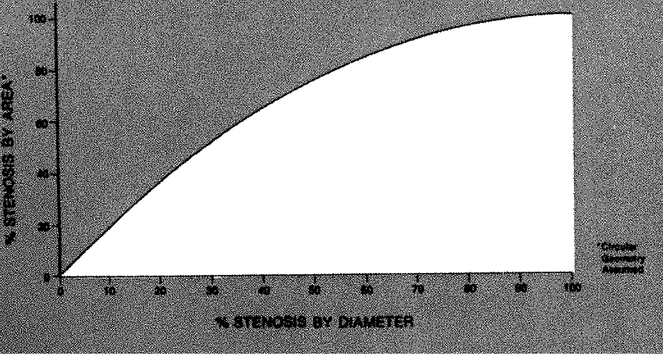
(CPA) for Cerebral Vascular evaluation



For
In-Hospital
use or
Office-Based
Practice.



% STENOSIS Dia.	By Area	DESCRIPTION	CPA TRACING
		1) Normal 1st and 2nd heart sounds with no significant audiofrequency content (amplitude, intensity) during either systole or diastole. Note: absence of only the 1st heart sound does not suggest abnormal carotid artery pathology	
		2) The first heart sound is obliterated: high frequency content is noted at the initiation of systole. As the lesion becomes more severe the audiofrequency content extends over a longer portion of systole	
		3) The 1st and 2nd heart sounds are obliterated: high frequency content is observed throughout systole and extends partially into diastole. As the lesion becomes more obstructive the audiofrequency content extends over a longer portion of diastole	
		4) When the lesion becomes severe enough to significantly reduce blood velocity, turbulence is also reduced, and the abnormal audiofrequency content is lost. In this case the CPA tracings may be normal. In some patients the heart sound amplitude is reduced.	



The major diagnostic CPA parameters are absence or presence of 1st and 2nd heart sounds, absence or presence of high-frequency content in systole or systole and diastole, and the differential character of the three traces taken on each side.

The sensitivity, amplification, quantitation, and frequency range of CPA is well above the capacity of the human ear. This allows appreciation of bruits that cannot be heard with a stethoscope. The advantages of quantitation and hard copy are obvious.

CPA is helpful even for the experienced examiner in identifying transmitted murmurs.

Patient groups most often suggested for routine Cerebral Vascular Evaluation include:

a) Hospital admissions over 60 years of age.
b) Patients undergoing cardiopulmonary bypass.
c) Patients with multiple risk factors for arteriosclerotic disease.

Deep venous incompetence (*DVI*): Thirteen limbs were included in this group because Doppler ultrasound demonstrated popliteal reflux. The ambulatory venous pressure was high (>45 mmHg) and was not affected by the venous cuffs. Superficial venous incompetence was also present in the majority of these patients.

Deep venous incompetence and occlusion (*DVI+DVO*): Eight limbs were included in this group because venography demonstrated occlusion of the iliofemoral segment and the ambulatory venous pressure was greater than 70 mmHg even when the venous cuffs were inflated.

Results

There was no significant difference in the mean venous volume of normal limbs, limbs with superficial venous incompetence and limbs with deep venous incompetence without occlusion. However, the mean venous volume of the limbs with deep venous occlusion was significantly lower and there was no overlap between this and the other groups (*Fig*. 2). The venous volume was always less than 1·5 ml/100 ml in the presence of deep venous occlusion and always higher than 2·0 ml/100 ml in the absence of occlusion.

The maximum venous outflow was always less than 55 ml 100 ml^{-1} min^{-1} in the presence of deep venous occlusion and more than 65 ml 100 ml^{-1} min^{-1} in the absence of occlusion. There was considerable overlap of the values of maximum venous outflow in the remaining three groups (*Fig*. 3).

The results of the ambulatory volume change are shown in *Fig*. 4. The mean ambulatory volume change was −2·20 (s.d. ± 0·5) in normal limbs. (The negative sign indicates that the calf volume is decreased.) The mean ambulatory volume change was −1·3 (s.d. ± 0·3) in limbs with superficial venous incompetence, −0·60 (s.d. ± 0·1) in limbs with deep venous incompetence and −0·06 (s.d. ± 0·5) in limbs with deep venous incompetence and occlusion. In the last group (DVI+DVO) the ambulatory volume change was negative and small (−0·25 ml/100 ml) in 6 limbs and positive (+0·40 ml/100 ml) (i.e. *calf volume increased*) in 2 limbs which belonged to patients with pain on walking. The ambulatory volume change was not affected by superficial venous occlusion in normal limbs and limbs with deep venous incompetence with or without occlusion, but it was brought into the normal range in the limbs with superficial incompetence only. Thus, the only overlap was between the group with deep venous incompetence and the group with deep venous incompetence and occlusion (*Fig*. 4).

The results of the refilling time studies are shown in *Fig*. 5. The refilling time did not demonstrate the same degree of separation between the groups as the ambulatory volume change because of considerable overlap.

There was a linear relationship between the ambulatory venous change and the ambulatory pressure change. The regression line and equation are shown in *Fig*. 6, in which the limbs with deep venous occlusion, limbs with deep venous incompetence and limbs with a normal deep venous system (ambulatory venous pressure and calf volume change measured with venous cuffs occluding the superficial veins) are shown as three completely separate groups.

Discussion

The maximum venous outflow reflects the functional capacity of the venous system to drain the blood collected in the lower limb during the period of venous occlusion. The venous volume is a measure of the venous capacity of the limb; its value reflects the space available for blood to accumulate. Both provide complete separation between limbs with and without deep venous occlusion and are of diagnostic value (*Figs*. 2, 3).

The ambulatory volume change without and with superficial venous occlusion provides information about the efficacy of the calf muscle pump, which depends on the state of the deep venous valves and on the patency of the deep venous system. In the limbs with superficial incompetence, when the superficial reflux was abolished and the efficacy of the calf muscle pump was restored by a below-knee cuff, the ambulatory volume change became normal. However, if deep reflux was present, even with associated superficial venous reflux, the value of the ambulatory volume change did not alter significantly after application of the venous cuffs. Thus, it was possible to achieve complete separation of normal limbs, limbs with superficial venous incompetence and limbs with deep venous incompetence.

The linear relationship (*Fig*. 6) between ambulatory volume change and ambulatory pressure change suggests that changes in calf volume vary according to changes in pressure. It also supports the validity of this non-invasive test.

By measuring the ambulatory volume change and either the maximum venous outflow or venous volume it is possible to produce complete separation of all four groups; i.e. it is possible to differentiate between normal limbs, limbs with superficial venous incompetence only, deep venous incompetence and deep venous incompetence with occlusion.

This is a useful screening test for limbs with suspected venous incompetence and is an aid in providing an accurate diagnosis without recourse to invasive tests. In addition, it provides a quantitative estimation of the degree of venous insufficiency. Possible future applications of this non-invasive method are the study of the natural history of deep venous thrombosis and post-phlebitic limb, the effect of elastic stockings, surgical treatment and sclerotherapy. It may also provide a better selection of patients with deep venous occlusion for reconstructive surgery.

Recent work on foot volume changes (Norgren, 1975; Annotation, 1978) during exercise suggests that useful information which correlates with the degree of venous insufficiency can be obtained. However, the results of foot volumetry show considerable overlap and cannot produce a complete separation of the various groups as achieved by calf volume plethysmography. In addition, foot volumetry does not provide a quantitative measure of the venous outflow. Foot volumetry will probably prove to be a simple screening test to identify limbs with venous insufficiency. Calf volume plethysmography is not only a screening test but also a test that can provide a precise diagnosis.

Axillary vein entrapment

A. H. BOONTJE*

SUMMARY

This paper describes a patient with right axillary vein obstruction resulting from compression of the vein due to anomalous muscle tissue extending from the latissimus dorsi muscle across the neurovascular bundle to the pectoralis major muscle. This 'axillopectoral muscle' causing entrapment of the axillary vein has been described in only a few cases. These previous reports are discussed, with special reference to the symptoms and phlebographic findings. The obstruction and the symptoms caused by it are intermittent; the phlebographic features are characteristic.

THE causes of venous obstruction in the upper limb have been divided into two groups. There may be primary effort thrombosis or secondary obstruction of the axillary or subclavian vein due to a trauma, compression caused by malignant processes or venous catheters. The obstruction described as primary, however, often proves to be secondary. In many of these cases there is a costoclavicular compression syndrome, but only rarely is there external compression, which is caused by various anomalies (Campbell et al., 1977). One such is a muscular anomaly consisting of muscle fibres extending from the latissimus dorsi muscle to the pectoralis major muscle. The following case report describes a patient with this rare condition, diagnosed preoperatively.

Case report

A woman aged 37 was referred to our university hospital with an 18-month history of heaviness and stiffness in the right arm of gradual onset. The patient found it virtually impossible to pursue her regular organ playing. The hand was usually somewhat swollen, especially at rest, and sometimes slightly discoloured. The patient slept poorly because of the disagreeable sensations, which persisted overnight. There had been no trauma to the arm.

Examination revealed that the right hand was slightly swollen. There was no discoloration. The venous patterns of the arms were symmetrical. No distended veins were visible on the right shoulder. The arterial circulation was normal. No bruits were audible in the neck. There were no clinical abnormalities in the arm nor in the axillary region.

General physical examination disclosed nothing unusual. There were no neurological abnormalities. The various pertinent studies with the arm in several different positions were all negative.

Phlebography of the right arm was then carried out (*Fig.* 1). This revealed a severe obstruction of the right axillary vein. A non-recanalized thrombosis seemed unlikely. Such a thrombosis as a rule results from costoclavicular compression and the venous obstruction was localized too distally. The next possible cause considered was compression of the axillary vein as a result of an aberrant muscle (Corning, 1949). Consequently, we decided upon surgical exploration.

The right axilla was opened by a longitudinal incision in the proximal part of the medial bicipital sulcus extending to the chest wall, curving along the edge of the pectoralis major muscle. The axillary vein was exposed. The calibre of this vein was normal from its distal part to just past the lower edge of the greater pectoral muscle, where a 1-cm hour-glass shaped stenosis was seen (*Fig.* 2). There was no thrombus. The venous wall was not thickened at the site of the stenosis. A taut band was present 0·5 cm cranial to the stenosis (*Fig.* 2). As the abducted arm was elevated, this taut band compressed the axillary vein precisely at the level of the stenosis. This band seemed to be the muscular anomaly mentioned above, and it ran from the latissimus dorsi muscle to the pectoralis major muscle.

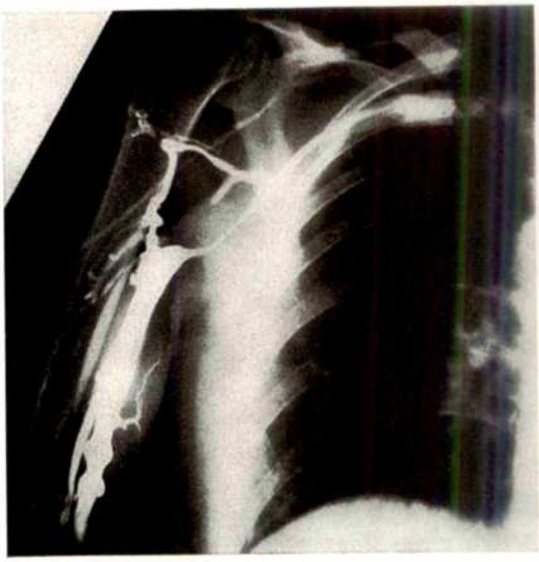

Fig. 1. Phlebography of the right arm. Almost complete occlusion of the axillary vein.

The band was resected. After some delay, the stenosed part of the axillary vein spontaneously resumed an acceptable calibre (*Fig.* 3). Patch angioplasty seemed unnecessary and the wound was closed in layers.

Microscopic examination of the resected specimen revealed striated muscle, thus confirming the diagnosis of a muscular anomaly.

The postoperative course was uneventful. Follow-up phlebography 2 weeks later revealed only a slight stricture of the axillary vein. The patient resumed her normal household duties, her complaints gradually disappeared and she was able to play the organ again.

Follow-up phlebography 6 months after the operation revealed excellent patency of the axillary vein without any constriction (*Fig.* 4), and the right hand no longer showed any signs of venous congestion.

Discussion

The symptoms and signs of obstruction of the axillary or subclavian vein are well known and consist of pain and tiredness in the arm, swelling, discoloration and an intensified venous pattern. This symptomatology is not specific for any particular cause of obstruction.

Phlebography may be required in axillary vein obstruction when no externally obvious cause is present. In some cases the site of venous obstruction is not at the level of the thoracic outlet, but more distal. Obstruction of the axillary vein caused by a muscular anomaly gives typical phlebographic features. The phlebogram of our patient (*Fig.* 1) is identical to that reproduced by Dodd and Cockett (1976). At the level of the lower axillary border the axillary vein shows a typically tapered stenosis, beyond which it gradually resumes its normal calibre. Two different muscular abnormalities can be distinguished. In most cases an aberrant muscle extends

from the latissimus dorsi muscle to the pectoralis major muscle and lies across the neurovascular bundle. This is known as *Langer'ser Armbogen* in German (Corning, 1949)—'Langer's arm arch' in English or the axillopectoral muscle (*Fig*. 5).

Rarely, aberrant muscle tissue extends from the latissimus dorsi muscle to the coracoid process—*Langer'ser Achselbogen* in German—'Langer's axillary arch'. Long-standing intermittent compression of the vein caused by this anomaly and dependent on the position of the arm can lead to venous thrombosis.

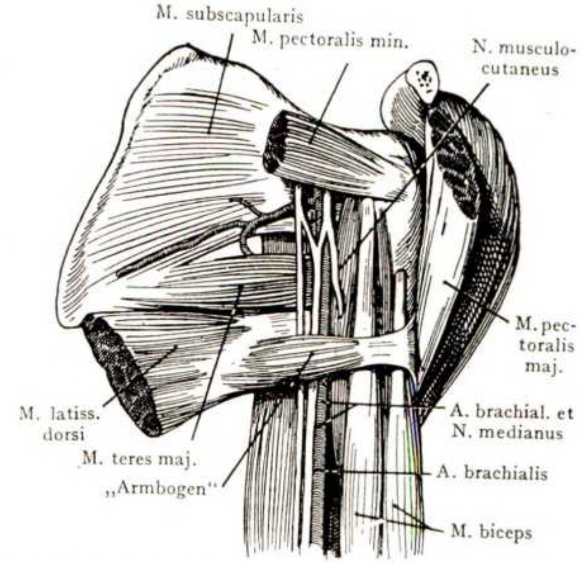

Fig. 5. Anatomy of the axilla with the axillopectoral muscle. (*From* Corning, 1949.)

It is likely that this anomaly is not as rare as it appears to be, but it is generally not diagnosed and explored. Apart from the case described by Dodd and Cockett (1976), Tilney et al. (1970) briefly mention a patient with this anomaly in a review article on venous thrombosis of the upper limb. Sachatello (1977) described a 15-year-old girl with intermittent swelling and discoloration of the hand caused by an axillopectoral muscle. Visible fullness in the axillary region was noticed in this patient. Both Tilney's and Sachatello's patient had a venous obstruction without thrombosis, and in both cases the aberrant muscle was resected.

Saitta and Baum (1962) described a boy aged 10 with a visible and palpable mass in the right axillary region, particularly during abduction of the arm. There was no evidence of venous obstruction. Exploration revealed that the mass was a muscular anomaly, which was resected.

Treatment of this problem is simple: after axillary exploration the aberrant muscle should be resected, thus abolishing the compression. Venous reconstruction can then be considered if a thrombus is present or if the venous wall is damaged.

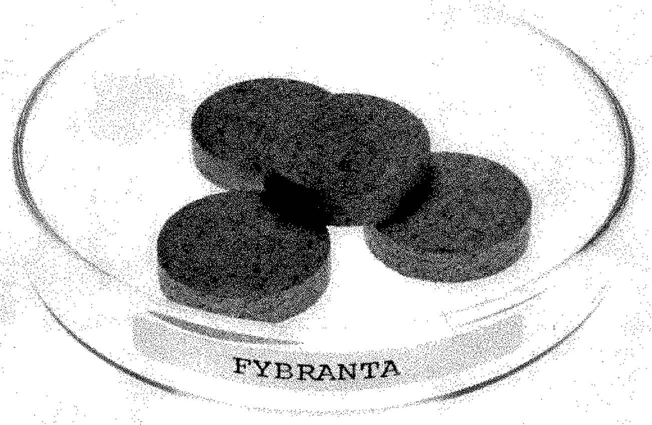
FYBRANTA
cereal fibre



The only fibre that does all it should

Fybranta contains unprocessed cereal fibre which has been clinically proved more effective than other widely used fibre treatments. Only cereal fibre significantly reduced transit time[1,2] and also lowered intraluminal pressure when tested against other substances[2] In addition, Fybranta was shown to be effective in increasing stool weight[1]

Partial and complete atrophy affecting hepatic segments and lobes

J. M. HAM*

SUMMARY
Thirty-four patients with atrophic lesions of liver segments or lobes are described. The primary diagnoses included alcoholic liver disease, various forms of cirrhosis, hydatid disease, tumours and sclerosing cholangitis. Seventeen patients had complete atrophy of the segment or lobe and the other 17 patients had partial atrophy (i.e. a reduction of at least 50 per cent in the size of the affected area). Complete atrophy affected the left lobe more frequently than the right. The condition is important, first, because it is more common than is generally recognized, and second, because it may create considerable diagnostic and therapeutic problems.

ATROPHIC lesions of the liver are usually regarded as pathological curiosities of little or no clinical importance (Benz et al., 1952; Bockus, 1965). However, these lesions have been seen quite frequently in this unit and in some patients they have created considerable diagnostic and therapeutic problems.

This report is concerned with 34 patients, 17 of whom had complete atrophy of a liver segment or lobe and 17, partial atrophy. There was a variety of primary diagnoses; these illustrate the fact that liver atrophy may be due to vascular or biliary obstruction, to direct hepatic cell injury or to combinations of these factors.

Definitions

Complete atrophy was diagnosed if the affected part of the liver was markedly shrunken and little or no normal liver tissue remained. Partial atrophy was defined as a reduction of at least 50 per cent in the size of a recognized anatomical segment or lobe. Patients with patchy areas of scarring and atrophy, such as are commonly seen in the various types of macronodular cirrhosis, were not included in the study.

The nomenclature of the hepatic segments was that described by Healey and Schroy (1953).

Pathological appearances

Complete atrophy: The macroscopic appearances of complete atrophy of the left lobe of the liver are illustrated in *Figs*. 1 and 2. The affected lobe was shrunken, firm and pink and was well demarcated from the right lobe. It measured 5 × 3 × 2 cm and thus was approximately one-tenth-of the size of a normal left lobe. The gross appearances of right lobe or segmental atrophy were similar to these. The microscopic features are illustrated by an operative liver biopsy (*Fig*. 3) taken from the left lobe of the liver shown in *Figs*. 1 and 2. There is almost complete absence of hepatocytes, proliferation of small bile ducts, considerable fibrosis and a patchy inflammatory cell infiltrate. Similar features were seen in the other patients with different causes of complete atrophy.

Partial atrophy: The macroscopic appearances differed only in degree from those described for complete atrophy. Microscopically, the features were also similar, except that there was some preservation of hepatocytes surrounded by broad bands of fibrous tissue.

Patients

These patients have all been seen personally over the past 7 years. The diagnosis was made in all cases except one (*Case* 3, *see below*) at operation or at autopsy, or both. The final diagnoses in the 34 patients are shown in *Table I*; these diagnoses were established pathologically in all cases except *Case* 3. *Cases* 1, 14, 15, 23, 25, 26, 28, 30, 31 and 32 have been reported previously (Ham, 1974; Ham et al., 1978).

In the following sections the features in the various groups of patients are summarized, together with descriptions of illustrative cases.

Table I: FINAL DIAGNOSES IN THE 34 PATIENTS

Alcoholic liver disease	7
Chronic active hepatitis with cirrhosis	7
Hydatid disease	7
Cryptogenic cirrhosis	4
Carcinoma of right hepatic duct	2
Sclerosing cholangitis	2
Viral hepatitis with acute liver failure	2
Hepatocellular carcinoma	1
Secondary biliary cirrhosis	1
Congenital hepatic fibrosis	1
Total	34

Alcoholic liver disease

The features of the 7 patients with alcoholic liver disease are shown in *Table II*. Six of the 7 patients had alcoholic cirrhosis, 4 with portal hypertension and oesophageal varices; the remaining patient had alcoholic hepatitis without cirrhosis, and chronic pancreatitis. The right lobe was affected in 4 patients and the left lobe in 3. In *Case* 3 the diagnosis was made clinically; on abdominal examination the liver was markedly enlarged in the epigastrium but impalpable in the right hypochondrium. A liver scintiscan demonstrated that most of the liver tissue was in the epigastrium, and there was no evidence of a space-occupying lesion in this region. Coeliac and superior mesenteric angiography demonstrated a marked reduction in the number and size of the arterial branches supplying the right lobe of the liver. The venous phase films showed that the right branch of the portal vein was much smaller than the left. Hepatic venography did not demonstrate an outflow block in either lobe.

Chronic active hepatitis

These 7 patients (*Table III*) all had associated macronodular cirrhosis, and 4 had portal hypertension requiring a shunt procedure. The right lobe was affected in 4 patients and the left lobe in 3.

Case 12: The macroscopic and microscopic appearances of the liver in *Case* 12 are shown in *Figs*. 1–3. This patient had known chronic liver disease and presented with portal hypertension and bleeding oesophageal varices. A liver scintiscan demonstrated little remaining hepatic tissue in the epigastrium. A subtraction film from the arterial phase of a coeliac angiogram is shown in *Fig*. 4; there is a marked reduction in the size and

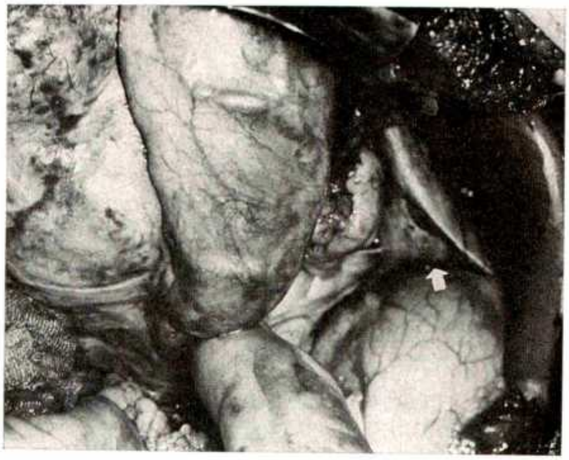

Fig. 1. Complete atrophy of the left lobe of the liver (arrow) in *Case* 12 demonstrated at operation. The gallbladder is in the centre of the picture.

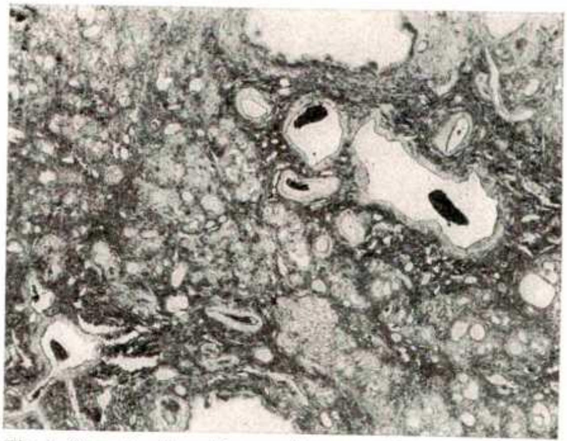

Fig. 3. Operative liver biopsy of the atrophic left lobe in *Case* 12. There is almost complete absence of hepatocytes (*see* text). (× 14.)

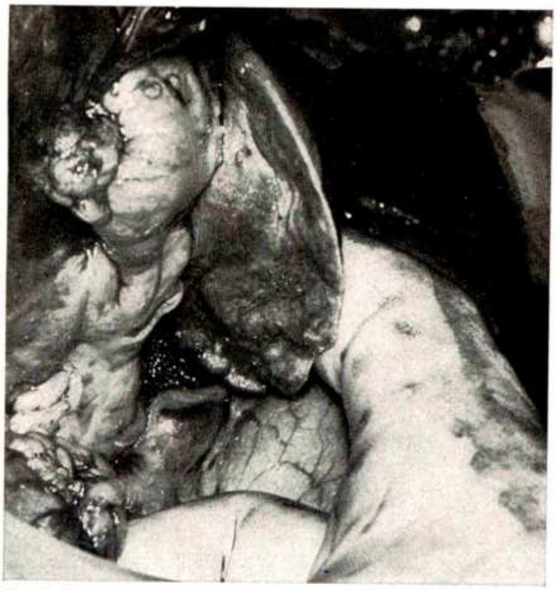

Fig. 2. Close-up view of the atrophic left lobe in *Case* 12.

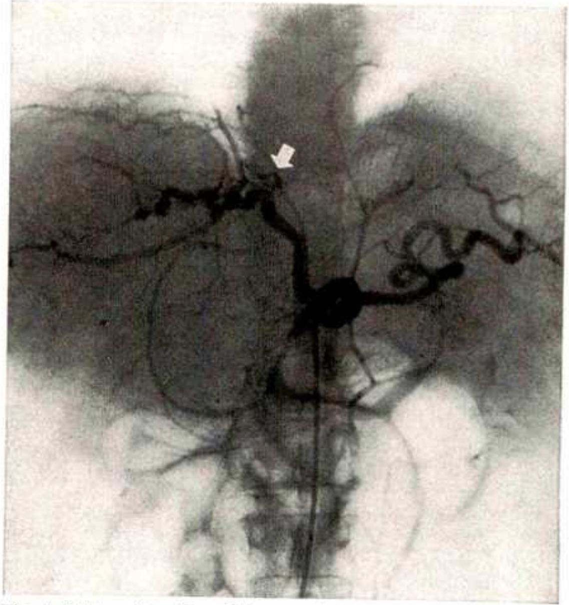

Fig. 4. Subtraction film of the arterial phase of a coeliac angiogram in *Case* 12. There is a marked reduction in the size and number of arteries supplying the region of the left lobe (arrow).

number of arteries supplying the region of the left lobe. In this patient, therefore, the diagnosis of complete left lobe atrophy was made preoperatively on the basis of these two investigations. The portacaval shunt procedure was technically difficult because of the gross distortion of the liver and displacement of the portal vein to the left away from the inferior vena cava.

Hydatid disease

These 7 patients had large single hydatid cysts in the right lobe (*Table IV*). Two patients had complete atrophy of all hepatic tissue in the right lobe and the remaining 5 had partial atrophy. In all 7 patients the left lobe was hypertrophied, this being most marked in the 2 with complete right lobe atrophy. In the latter patients, the left lobe was enlarged to the size of a normal liver.

Case 18: At operation *Case* 18 was found to have a large cyst (15 cm in diameter) in the upper part of the right lobe and what liver tissue remained in this lobe was shrunken. There was a sharp demarcation between the right and left lobes, partly because of the shrinkage of the right lobe and partly because of the enlargement of the left lobe. The liver scintiscan in this patient corresponded closely with these findings.

Cryptogenic cirrhosis (*Table V*)

Four patients had cryptogenic cirrhosis. *Case* 25 had complete atrophy of the medio-superior and medio-inferior segments of the left lobe, producing a deep cleft between the remaining left lobe segments and the right lobe. At autopsy this patient was found to have dilated bile ducts in these segments caused by a malignant hepatoma 5 cm in diameter arising in the quadrate lobe.

Carcinoma of right hepatic duct (*Table VI*)

Case 27, a woman of 22, presented with progressive obstructive jaundice. A percutaneous transhepatic cholangiogram demonstrated dilated ducts in the right lobe thought to be due to malignant obstruction of the right hepatic duct. The ducts were 'crowded' together, reduced in length and displaced to the right.

Table II: PATIENTS WITH ALCOHOLIC LIVER DISEASE

Case no.	Sex	Age (yr)	Affected part of liver	Partial or complete atrophy	Remainder of liver	Treatment
1	M	44	Left lobe	Complete	Enlarged, alcoholic hepatitis	Drainage of pancreatic abscess
2	F	63	Left lobe	Partial	Cirrhosis	Medical
3	M	57	Right lobe	Complete (?)	Cirrhosis	Medical
4	M	67	Right lobe	Partial	Cirrhosis	Portacaval shunt
5	M	54	Right lobe	Partial	Cirrhosis	Portacaval shunt
6	M	47	Right lobe	Partial	Cirrhosis	Portacaval shunt
7	M	46	Left lobe	Complete	Cirrhosis	Portacaval shunt

Table III: PATIENTS WITH CHRONIC ACTIVE HEPATITIS

Case no.	Sex	Age (yr)	Affected part of liver	Partial or complete atrophy	Remainder of liver	Treatment
8	M	72	Right lobe	Complete	Cirrhosis	Laparotomy only
9	M	51	Left lobe	Complete	Cirrhosis	Portacaval shunt
10	M	47	Right lobe	Partial	Cirrhosis	Medical
11	F	49	Right lobe	Partial	Cirrhosis	Exploration common bile duct
12	M	37	Left lobe	Complete	Cirrhosis	Portacaval shunt
13	F	58	Right lobe	Partial	Cirrhosis	Portacaval shunt
14	F	34	Left lobe	Complete	Cirrhosis	Portacaval shunt

Table IV: PATIENTS WITH HYDATID DISEASE

Case no.	Sex	Age (yr)	Affected part of liver	Partial or complete atrophy	Remainder of liver	Treatment
15	F	52	Right lobe	Complete	Hypertrophy	R hepatic lobectomy
16	F	21	Right lobe	Partial	Hypertrophy	Evacuation of cyst: omentopexy
17	F	19	Right lobe	Partial	Hypertrophy	Evacuation of cyst: omentopexy
18	F	47	Right lobe	Partial	Hypertrophy	Evacuation of cyst: omentopexy
19	F	34	Right lobe	Partial	Hypertrophy	Evacuation of cyst: omentopexy
20	M	59	Right lobe	Complete	Hypertrophy	Evacuation of cyst: partial liver excision
21	M	36	Right lobe	Partial	Hypertrophy	Evacuation of cyst: omentopexy

Table V: PATIENTS WITH CRYPTOGENIC CIRRHOSIS

Case no.	Sex	Age (yr)	Affected part of liver	Partial or complete atrophy	Remainder of liver	Treatment
22	F	55	Right lobe	Partial	Cirrhosis	Portacaval shunt
23	M	47	Left lobe	Complete	Cirrhosis	Portacaval shunt
24	F	59	Left lobe	Partial	Cirrhosis	Portacaval shunt
25	M	49	Medio-superior and medio-inferior segments left lobe	Complete	Cirrhosis, hepatoma in quadrate lobe	Cholecystectomy, exploration of common bile duct

Table VI: MISCELLANEOUS GROUP

Case no.	Sex	Age (yr)	Diagnosis	Affected part of liver	Partial or complete atrophy	Treatment
26	F	59	Carcinoma right hepatic duct	Right lobe	Complete	Laparotomy and biopsy
27	F	22	Carcinoma right hepatic duct	Right lobe	Partial	Right hepatic lobectomy
28	M	32	Sclerosing cholangitis	Latero-inferior segment left lobe	Complete	T tube drainage, steroids
29	M	62	Sclerosing cholangitis	Right lobe	Partial	T tube drainage, steroids
30	F	70	Viral hepatitis	Left lobe	Complete	Exchange blood transfusion
31	F	56	Viral hepatitis	Left lobe	Complete	Pig liver perfusion
32	F	30	Hepatocellular carcinoma	Right lobe	Partial	Right hepatic lobectomy
33	M	32	Secondary biliary cirrhosis (benign bile duct tumour)	Latero-inferior segment left lobe	Complete	Biliary bypass
34	M	16	Congenital hepatic fibrosis	Latero-inferior segment left lobe	Complete	Portacaval shunt

Subsequent films of the left lobe ducts demonstrated partial obstruction of the left hepatic duct at the junction of the right and left ducts. It was felt that resection of the tumour was possible, there being sufficient uninvolved left hepatic duct to carry out an anastomosis to a jejunal segment. At operation partial atrophy of the right lobe was found. A right hepatic lobectomy and resection of the tumour was performed.

Sclerosing cholangitis (*Table VI*)

One of these patients (*Case* 28) had atrophy of the latero-inferior segment of the left lobe and a T tube cholangiogram demonstrated obstruction of the bile duct draining that segment (Ham, 1974). The second patient (*Case* 29) presented with severe cholestasis. A percutaneous transhepatic cholangiogram demonstrated partial obstruction of the right hepatic duct and secondary obstructions of smaller ducts in the right lobe. The operative and pathological findings were compatible with the diagnosis of sclerosing cholangitis and there was partial atrophy of the right lobe of the liver.

Remaining patients

Case 32 had a large hepatocellular carcinoma in the upper part of the right lobe with partial atrophy of the remaining uninvolved liver tissue. The patient did not have cirrhosis, and there was evidence that the tumour may have been induced by oral contraceptives (Ham et al., 1978).

Case 33 presented with prolonged cholestasis. A percutaneous transhepatic cholangiogram was interpreted as demonstrating malignant obstruction at the ampulla. The operative findings included biliary cirrhosis, atrophy of the latero-inferior segment of the left lobe and a benign tumour at the lower end of the common bile duct. These findings were confirmed histologically.

The final patient (*Case* 34) presented with portal hypertension and bleeding oesophageal varices. The diagnosis of congenital hepatic fibrosis and segmental atrophy was confirmed by operative biopsy.

Summary of data

There were 17 patients with complete atrophy and 17 with partial atrophy. The lesion involved the right lobe in 20 patients, the left lobe in 10 and hepatic segments in 4. Segmental atrophy was only seen in the left lobe and was always complete.

There were 17 patients with cirrhosis due to primary hepatocellular disease (*Tables II, III* and *V*). The right lobe was atrophic in 9 of these patients and the left in 8. However, only 2 of the former group had complete atrophy, whereas complete atrophy was present in 6 of the 8 affected left lobes.

Hypertrophy of the unaffected hepatic segments or lobes was a striking feature in those patients with space-occupying lesions, i.e. hydatid cysts and hepatic tumours. It was much less common in those with cirrhosis or other diffuse hepatic disease.

Precise aetiological factors were difficult to determine in many patients. However, obstruction of the bile ducts draining the affected segment or lobe was demonstrated in the 2 patients with carcinomas of the right hepatic duct (*Cases* 26 and 27), the 2 patients with sclerosing cholangitis (*Cases* 28 and 29) and *Case* 25, who had cryptogenic cirrhosis and a hepatoma. There was no definite proof of vascular or biliary obstruction in any of the other patients.

Discussion

Benz et al. (1952) described liver atrophy as an incidental curiosity encountered at necropsy and Bockus (1965) suggested that it was of little clinical significance. By contrast, Braasch et al. (1972) have described 4 patients with strictures of bile ducts draining a liver segment or lobe and accompanying atrophy. Galloway et al. (1973) have demonstrated atrophy in unilobar venous outflow obstruction, and Hueston (1963) has reported atrophy in association with hydatid disease. There are also descriptions of liver atrophy in the various forms of cirrhosis (Baggenstoss and Stauffer, 1952; Benz et al., 1952). Thus, these reports and the experience with the present series of patients suggest that the condition is more common than is generally recognized.

It is also clear that the clinician treating patients with hepatobiliary disorders must have a knowledge of these abnormalities. The potential difficulties they may create in the interpretation of the findings on physical examination and the results of investigations are well illustrated by the patients presented here. It has been stressed by Soloway et al. (1971) and Scheuer (1973) that hepatic disease is frequently uneven in its distribution, which may result in significant sampling errors when hepatic disease is assessed by percutaneous needle biopsy. Atrophic lesions are clearly one cause of such sampling errors. The surgeon who observes these abnormalities during laparoscopy or laparotomy must be aware of their causes and significance in order to obtain the appropriate biopsies and plan the patient's management.

The findings in *Case* 3 illustrate that the diagnosis may be suspected on physical examination when hypertrophy of one lobe is associated with atrophy of the other. Most commonly, differential enlargement of the liver in the epigastrium or right hypochondrium will suggest an abnormality in that region of the liver, e.g. a Riedl's lobe, tumour or cyst. However, the enlargement may be caused by hypertrophy of the normal lobe while the abnormality is in the impalpable lobe. These were the physical findings in a number of patients in this series, notably those with hydatid disease and bile duct tumours.

With increasing experience, we have suspected the diagnosis more frequently on examining liver scintiscans, although only gross lesions are evident. There is usually little or no isotope uptake in an atrophic lobe and only patchy uptake in a partly atrophic region. However, in many of our patients the diagnosis could only be suspected, even when the scintiscans were reviewed with full knowledge of the diagnosis.

It was difficult to distinguish between the anatomical right and left lobe on the scintiscan of many of the cirrhotic patients because of liver distortion and the lack of an easily identifiable gallbladder impression. In the patients with hydatid disease the scintiscans were much easier to interpret, the findings being a large filling defect in the right lobe, little or no uptake in the remaining right lobe and the left lobe approximating the size of a normal liver. As might be expected, it was difficult to detect areas of segmental atrophy. However, atrophy of the medial segments of the left lobe was demonstrated in *Case* 25 (Ham, 1974). It is obviously important for those interpreting liver scintiscans to be aware that liver atrophy may produce an appearance compatible with that of a space-occupying lesion, and consequently a misdiagnosis of liver tumour may be made. This error occurred in 2 patients in this series.

Coeliac and superior mesenteric angiography with venous phase films provides much useful information and may be diagnostic in patients with complete lobar atrophy. Early in this series we failed to appreciate the changes demonstrated. In the more recent patients, however, we have recognized that lobar atrophy is associated with a reduction in the number of arteries supplying the affected lobe, and those arteries which are seen are 'crowded' and tortuous. Both arteries and veins are reduced in size, sometimes markedly (*see Fig.* 4). The affected region is relatively avascular. There may be displacement of the vessels in the unaffected lobe towards the affected side, and the unaffected lobe may be enlarged.

The bile ducts in an atrophic lobe may also be displaced to the affected side and 'crowded' together. Dilatation of the ducts is an important finding since the patient may have a surgically correctable lesion.

The causes of liver atrophy have been discussed in detail by Rous and Larimore (1920), Himsworth (1947) and by Schalm et al. (1956). These authors have stressed the great variety of possible causes, including vascular or bile duct obstruction and direct liver injury caused by viruses, toxins or nutritional factors. In some patients, more than one of these factors may be important.

The experimental studies of Schalm et al. (1956) on segmental and lobar biliary obstruction have demonstrated that such lesions are regularly accompanied by atrophy of the appropriate region of the liver and hypertrophy of the remainder. Thus, the pathological changes are similar to those in patients with obstruction of an intrahepatic bile duct. However, they are not identical, because the experimental models are usually created by acute ductal obstruction, whilst in man the clinical features are more often the result of progressive, slow biliary obstruction. Biliary obstruction was positively identified in 5 patients in this series (*Cases* 25, 26, 27, 28, 29). It was probably a factor in *Cases* 32 and 33 and in the 7 patients with hydatid disease. However, it is likely that the latter 9 patients had vascular obstruction as well.

The cause of the atrophy in the patients with primary hepatocellular disease is uncertain, but presumably it followed hepatic cell damage and necrosis. It is not clear, however, why the effect should be lobar or segmental. In addition, the left lobe seemed to be disadvantaged as compared to the right; segmental lesions were only observed in the left lobe and, although approximately equal numbers of patients had right and left lobe lesions, a greater proportion of the left-sided lesions was complete. This suggests that the left lobe may be more vulnerable to damage, or that its ability to recover following injury is impaired. The experiments of Starzl et al. (1973) have demonstrated the importance of the biochemical environment of different liver regions in maintaining hepatic homeostasis. Specifically, they demonstrated that the substances responsible for hepatic hypertrophy, hyperplasia, glycogenation and weight gain were derived from the pancreatic–gastroduodenal–splenic venous drainage. They concluded that these hepatotrophic substances were insulin and glucagon. An absolute or relative lack of these, or of other hepatotrophic factors, may have been important in the pathogenesis of the lesions seen in some of these patients.

Such a mechanism is not easy to understand in patients with diffuse hepatic disease, but it is possible that during the acute phase of liver injury the portal blood flow to certain regions of the liver may be compromised, perhaps due to acute liver enlargement. The combination of reduced portal blood flow and the factor causing the acute injury might result in liver cell necrosis and subsequent atrophy.

Whatever their cause, these lesions certainly indicate serious hepatic disease, either local or diffuse. Suggestions regarding treatment have been outlined previously (Ham, 1974) and it is stressed again that the only treatable causes of liver atrophy are those associated with bile duct obstruction or space-occupying lesions.

The treatment of major liver trauma by primary packing with transfer of the patient for definitive treatment

R. Y. CALNE, P. McMASTER AND B. D. PENTLOW*

SUMMARY

Four patients are reported in whom massive haemorrhage from severe hepatic trauma was managed initially by conservative surgery and packing. The patients were then transferred by ambulance to Addenbrooke's Hospital where further treatment involved elective surgery and removal of packs. All 4 patients were discharged from hospital and have made full recoveries. It is felt that the management of liver trauma should be to do the minimum that is necessary to staunch bleeding, by suture, arterial ligation, lobectomy, resectional débridement or simply by packing. This allows the patient's haemodynamic state to be restored to normal before further surgery is attempted.

THE incidence of major liver trauma is increasing (Aronsen et al., 1968; Walt, 1974). With an efficient ambulance service and improved methods of resuscitation, patients who would previously have died *en route* to hospital or in the accident service are surviving long enough for surgical treatment. In an excellent review on hepatic trauma, Walt (1978) refers to 5 patients who appeared to be exsanguinating before the insertion of packs, yet all recovered and were discharged from hospital. Even in large hospital centres with expert anaesthetists, continuous patient monitoring and unlimited supplies of banked blood, major hepatic trauma involving the hepatic veins and vena cava has an extremely high mortality (Wilson, 1963; Schrock et al., 1968). We report here a personal series of 4 consecutive cases referred to Addenbrooke's Hospital in whom massive exsanguinating haemorrhage could only be controlled by packing with gauze rolls. Undoubtedly, the patients owe their lives to this procedure, which enabled their safe transfer and subsequent management, so that all were able to leave hospital and return to normal health and full rehabilitation.

We endorse Walt's view that 'The judicious surgeon who choses this method should in no way fear the whispered loss of his surgical manhood' (Walt, 1978).

Case reports

Case 1: M. W., a male aged 16, was admitted on 3 June 1971. He had been sleeping in a field when his abdomen was crushed by the wheels of a Land Rover. Laparotomy revealed extensive lacerations to the right lobe of the liver. Attempts at haemostasis by suturing over Surgicel did not control the bleeding. The area around the liver was packed with gauze rolls and the patient was transferred to Addenbrooke's Hospital. On arrival 14 h after injury he had received 20 units of blood and was in a shocked state with a grossly distended abdomen. He was taken to theatre and the laparotomy incision was extended into the right chest, through the eighth intercostal space. A large amount of clotted and liquid blood was removed from the abdominal cavity. Most of the right lobe had been avulsed and was ischaemic. The hepatic artery and portal vein were cross-clamped and a right hepatic lobectomy was performed, the operation mainly consisting of removal of the necrotic liver and suturing of exposed blood vessels. Postoperative intensive care required bronchoscopy, mechanical ventilation for 48 h and repeated aspiration of pleural effusions. The patient was discharged from hospital 3 weeks after operation and has remained well.

When last seen on 4 October 1973 the liver scan showed regeneration over the liver to full size and the patient was leading a perfectly normal life as a member of the Royal Air Force.

Case 2: B. D., a female aged 36, was admitted on 16 December 1975 after having been knocked off her moped by a car. In addition to abdominal injuries, there were haematomas over the left orbit, chest, right arm and leg, the left little finger and wrist were fractured and there was a laceration of the right thigh. Laparotomy revealed 6 l of intraperitoneal blood and extensive lacerations into the right lobe of the liver.

Bleeding was controlled by packing the lacerations with Surgicel and gauze rolls and by hepatic arterial ligation beyond the gastroduodenal artery. By the time of admission to Addenbrooke's Hospital 24 h later she had received 28 units of blood. She was normotensive and passing urine, but had a pulse rate of 160 and CVP of -6 cmH$_2$O. Prothrombin time was 32 s (control 16 s), platelets 62×10^9/l, blood sugar 90 (5 mmol units).

After 18 h of intensive resuscitation with blood, platelets and fresh frozen plasma, laparotomy was performed extending the incision into the chest via the eighth intercostal space. A large quantity of old blood was removed, as were the packs There were deep lacerations in the right hepatic lobe, most of which was necrotic, as was the gallbladder. The left lobe was pale. Right partial hepatectomy was performed; removal of the ligature from the common hepatic artery did not produce pulsation. Arteriotomy revealed a fractured intima. This was repaired and the defect closed with a small patch taken from the right inferior epigastric artery. A good pulse was restored and the remaining liver took on a normal colour.

The patient required postoperative mechanical ventilation for 24 h. Liver function was temporarily deranged, the bilirubin rising to 162 μmol and the SGPT to 1152. The patient recovered from the other associated injuries.

When last seen on 1 March 1978, more than 2 years after the accident, the patient had normal liver function, no neurological defects and was in excellent health.

Case 3: T. v. N. a male aged 34, was admitted on 8 October 1974. He had developed signs of severe blood loss after suffering an upper abdominal stab wound. Laparotomy revealed a severe penetrating wound in the liver. Bleeding was temporarily controlled, but continued haemorrhage necessitated a further operation 24 h later. Bleeding was controlled by insertion of packs into a necrotic area in the right lobe of the liver. The patient was transferred to Addenbrooke's Hospital. The old wound was reopened and the incision was extended into the chest via the ninth intercostal space. The knife had penetrated the right lobe, within which was a large cavity containing blood clot. The liver superficial to this was of doubtful viability The haematoma was evacuated, some débridement performed and haemostasis secured. Large drains were inserted into the cavity.

Artificial ventilation was necessary for 24 h but events thereafter were relatively smooth. When the patient was last seen on 17 September 1975 there was no residual disability. One year after admission a liver scan showed a 5-cm 'scarred' area in the right lobe. The patient had returned to work.

Case 4: S. A., a male aged 22, was admitted on 15 September 1976 after being involved in a collison whilst riding a motor cycle. He had sustained abdominal injuries. Laparotomy revealed a massive haemoperitoneum with bleeding continuing from a tear in the gallbladder bed and porta hepatis. There was a hole in the portal vein. Bleeding was controlled by suture of the portal vein; the gallbladder was removed. Postoperative recovery was complicated by a pleural effusion thought to be secondary to a subphrenic abscess. Three weeks after injury the patient suddenly collapsed in a state of shock. At re-exploration blood welled up from the porta hepatis. Bleeding was controlled by packing and the patient was transferred, still under general anaesthesia, to Addenbrooke's Hospital where the wound was reopened. Two litres of blood clot were removed from around the liver. The principal site of bleeding was a 5-mm hole in the anterior wall of the portal vein, which was repaired with Prolene sutures. Bleeding from the tear into the liver stopped after evacuation of clot. An unidentified biliary radical was damaged during exploration, and because of this a T tube was inserted into the common bile duct. Drains were inserted into the hepatic laceration. After mechanical ventilation for 24 h the patient's course was uneventful. The T tube was left *in situ* for 9 weeks.

---

* Department of Surgery, University of Cambridge.

When last seen on 21 June 1978 there was no residual disability and the patient had returned to work.

Discussion

These 4 patients all had potentially lethal hepatic injuries. Primary surgical treatment did not stop the haemorrhage and packing was resorted to as a life-saving procedure. The fact that the patients survived the packing and were transferred to Addenbrooke's Hospital implies selection, but they were all gravely ill and had suffered from severe blood loss. In this period from 1971 to 1978 there have been no other patients similarly treated by packing and then referred to the Department of Surgery in Cambridge who have failed to survive the journey. It has been our policy to attempt early definitive surgery on patients admitted primarily to our hospital with massive haemorrhage from the liver. An unsuccessful outcome has most often been due to hepatic venous bleeding. Death has rapidly followed laparotomy, presumably owing to release of the blood clot tamponade of the venous tear, following relaxation of the abdominal muscles and the abdominal incision.

From a consideration of the cases reported here, it would appear that there is a marked advantage to a patient who has sustained massive haemorrhage from liver trauma if a period for resuscitation can be achieved. During the course of a few hours, if rapid bleeding has been contained, blood loss can be replaced and the patient's haemodynamic equilibrium restored, before any further surgical intervention. Madding and Kennedy (1965) cautioned against packing liver injuries. Most of their cases were penetrating war wounds, often treated after considerable delay when sepsis was already established. We feel that with civilian casualties and rapid transfer to hospital the danger of sepsis in the presence of packs and devitalized liver tissue is less of a risk than continuing primary haemorrhage during emergency definitive surgery.

Conclusions

We believe that the management of liver trauma should be as conservative as possible. At laparotomy suture of lacerated liver and ligation of bleeding vessels is the first procedure. Bleeding from infrahepatic caval injuries can usually be controlled by direct suture. If arterial bleeding continues, selective hepatic artery ligation is undertaken distal to the gastroduodenal artery and cholecystectomy may be necessary. If, after suturing the lacerations, there is continuous venous bleeding from deep traumatic clefts which may involve the retroperitoneal vena cava, then large rolls of gauze are inserted into the depth of the wound without any further dissection of ligamentous attachments of the liver. The aim is to secure tamponade of venous lacerations. If this succeeds in stabilizing the patient's condition, the wound is closed and monitoring continued in the intensive care unit with a view to removing the packs and performing further laparotomy with removal of devitalized tissue, wound drainage and possible hepatic resection 2–3 days later. Broad spectrum antibiotics are administered systemically. If bleeding is not controlled by ligation and/or packing, the scale of the operation escalates, so that it becomes a major procedure. A definitive major lobar resection may succeed in saving a patient with trauma confined to one lobe. A tear of the hepatic veins or of the vena cava close to the hepatic veins can be extremely difficult to control because of bleeding preventing the lesion from being seen. To obtain a bloodless field the hepatic arterial and portal venous inflow must be clamped and the vena cava above and below the liver controlled (McMaster, 1977). Access to the cava above the liver can be obtained via the pericardium by splitting the sternum, and venous shunts may be required (Miller, 1972; Trunkey et al., 1974). This type of heroic surgery has an extremely high mortality even in skilled hands, but a successful outcome is possible (Waltuck et al., 1970).

On the basis of this limited experience from the cases reported here, we consider that the most important objective is to secure primary control of haemorrhage, whether by suture, hepatic arterial ligation, lobectomy, resection débridement or temporary packing. This permits a period of resuscitation which may be all important to the patient's life.

Postoperative hypophosphataemia

P. C. ENGLAND, M. DUARI, D. E. F. TWEEDLE, R. A. JONES AND E. GOWLAND*

SUMMARY

The possible mechanisms of postoperative hypophosphataemia were studied in women undergoing uncomplicated cholecystectomy. Six patients were allocated to each of three groups. Group I received no intravenous fluids, group II received dextrose/saline solution alone and group III received dextrose/saline solution with phosphorus supplementation. The serum concentration of inorganic phosphorus fell in all three groups, the greatest fall being in the group receiving dextrose/saline solution. However, the lowest level reached (0·82 mmol/l) was within the normal range for our laboratory. Concentrations of red blood cell adenosine triphosphate and 2,3-diphosphoglycerate showed similar changes. The operations were not associated with a large catabolic response nor with an increase in urinary phosphorus excretion. The postoperative reduction in serum concentration of inorganic phosphorus appeared to be due mainly to haemodilution. There is no indication for routine phosphorus supplementation following uncomplicated elective surgery.

HYPOPHOSPHATAEMIA reduces the content of 2,3-diphosphoglycerate and adenosine triphosphate in red blood cells (Travis et al., 1971). As a consequence, haemoglobin has an increased affinity for oxygen and this hinders the release of oxygen in the tissues. Hypophosphataemia may also produce a severe haemolytic anaemia (Jacob and Amsden, 1971; Klock et al., 1974). Both these mechanisms contribute to dangerous tissue hypoxia. Hypophosphataemia is a well-recognized complication of intravenous feeding regimens containing high concentrations of dextrose (Groen et al., 1952; Travis et al., 1971), chronic alcoholism (Territo and Tanaka, 1974), septicaemia (Riedler and Schietlin, 1969), and in patients undergoing renal dialysis (Mahony et al., 1976). Hypophosphataemia has been reported recently following the routine postoperative infusion of dextrose/saline solution (Guillou et al., 1976). However, the plasma inorganic phosphorus concentration fell not only in patients who received dextrose/saline but also in those who received saline alone, and rose again to preoperative concentrations despite the continuation of the infusion. These observations suggested that some factor other than the dextrose infusion was contributing to the hypophosphataemia. Furthermore, the clinical significance of these findings is uncertain as the concentration of plasma inorganic phosphorus did not fall to levels associated with clinical signs or symptoms, and red blood cell concentrations of 2,3-diphosphoglycerate and adenosine triphosphate were not measured. It is these organic, intracellular compounds that are of importance in inducing changes in the oxygen dissociation curve (Travis et al., 1971).

This study was undertaken to examine the possible mechanisms of hypophosphataemia in women following elective cholecystectomy and to ascertain whether this has any clinical significance.

Patients and methods

Eighteen female patients undergoing elective cholecystectomy without exploration of the common bile duct were admitted 48 h before surgery and their informed consent to the study was obtained. None of the patients studied was taking the contraceptive pill or other hormonal preparation. Six patients were allocated to each of three groups. Group I patients received no intravenous infusion; group II patients received 2·5 l of 4 per cent dextrose and 0·18 isotonic saline and 40 mmol of potassium chloride; and group III patients received 2·5 l of 4 per cent dextrose and 0·18 per cent isotonic saline, 10 mmol of potassium chloride and 30 mmol of potassium dihydrogen phosphate. Samples of venous blood were taken preoperatively and postoperatively at the end of each 24-h period of study. Similarly, 24-h collections of urine were obtained. The samples were analysed on Technicon SMA 12/60 and SMA 6/60 analysers for serum inorganic phosphorus and calcium, serum and urinary urea and creatinine, serum albumin and packed cell volume. Urinary calcium and phosphorus assays were performed manually. Phosphorus

determination was by the molybdovanadate method. Red blood cell content of 2,3-diphosphoglycerate and adenosine triphosphate was estimated using commercial kits (Boehringer Mannheim GmbH).

The 24-h periods of study have been designated preop. (preoperative), op. (day of operation) and day+1 to day+3 (postoperative). The results were analysed using Student's *t* test for paired data within the groups and Student's *t* test for unpaired data between the groups.

Results

The three groups studied were comparable in age and weight distribution. The mean (and standard deviation) ages and weights of the patients were: in group I, 45·7±15·6 years and 57·5±6·8 kg; for group II, 46·5±21 years and 67·2±10 kg; and for group III, 55·2±6·7 years and 63·2±14 kg.

Serum concentrations of inorganic phosphorus fell in all three groups, reaching the lowest value of 0·82 mmol/l on the day of operation in group II and on day+1 in groups I and III (*Fig.* 1). These falls were statistically significant in all groups when compared with the respective preoperative concentrations ($P<0{\cdot}05$). Following these falls, the concentrations of inorganic phosphorus rose, regaining preoperative concentrations by day+3. The only significant difference between the groups was on the day of operation, when the concentration in group II was significantly lower than that in the other two groups ($P<0{\cdot}05$). There were small and divergent fluctuations in the red blood cell concentration of 2,3-diphosphoglycerate in all groups. In group II there were significant falls in the concentration on the day of operation, on day+1 and day+3 when compared with the preoperative concentration ($P<0{\cdot}01$). There were no intergroup differences. The red blood cell concentration of adenosine triphosphate fell in all groups (*Fig.* 2) and reached statistical significance in groups I and II ($P<0{\cdot}05$). On day+2 the fall in concentration of adenosine triphosphate in group II was significantly greater than that in group III ($P<0{\cdot}01$). The concentration of serum albumin fell in the three groups, reaching significance on day +1 to day+3 ($P<0{\cdot}01$). There were no significant differences between the groups. The packed cell volume also fell in the three groups studied (*Fig.* 3) but, owing to the wide range of results, this reached significance only in group I on day+1 and day+2 ($P<0{\cdot}05$). The concentration of serum urea rose in patients in group I who did not receive intravenous fluids but fell in the two groups that did, reaching significance in group III on day+1 to day+3 ($P<0{\cdot}01$). Serum concentrations of creatinine followed a similar trend. There were no significant changes in the concentration of serum calcium in any of the groups studied. There was no increase in the urinary excretion of inorganic phosphorus in groups I and II but in group III, who received phosphorus supplementation, there was a marked increase (*Fig.* 1), reaching

significance on the day of operation and day+1 ($P<0·05$). There were no significant changes in the urinary excretion of urea, creatinine or calcium in any of the groups studied.

Discussion

The concentration of serum inorganic phosphorus fell significantly after surgery in all groups, indicating that some mechanism other than the simple postoperative infusion of dextrose fluids was responsible. The greatest fall, however, did occur in the group receiving dextrose/saline solution alone, but the concentrations were still well within the normal range for this laboratory and not as low as those reported by others (Guillou et al., 1976). In keeping with other reports (Guillou et al., 1976; Rowlands and Giddings, 1976), the concentration of serum inorganic phosphorus had reached preoperative values within 3–4 days of operation. Postoperative hypophosphataemia in well-nourished patients would appear to be a transient and self-limiting phenomenon and probably of little clinical significance. Further, the small falls in the red blood cell concentration of 2,3 diphosphoglycerate and adenosine triphosphate found in this study were within the normal range and unlikely to cause any significant shift to the left of the oxygen dissociation curve. There was no increase in the urinary excretion of inorganic phosphorus in the two groups that did not receive phosphorus supplementation.

Similarly, there was no increase in the urea excretion, indicating little protein catabolism following these elective operations. The group that received phosphorus supplementation had a large increase in urinary excretion of phosphorus. Although the overall phosphorus balance was improved when compared with the other two groups, it was still negative. Serum albumin and packed cell volume estimations are indicators of haemoconcentration and, in view of the insignificant operative and postoperative loss, the results suggest that a moderate degree of haemodilution occurred in all three groups.

The postoperative falls in the group that received no intravenous fluid were surprising. It has been reported that postoperative haemodilution is a consequence of water retention (Le Quesne, 1954). However, this group had an oral intake of approximately 300 ml and 600 ml of water and a mean urinary output of 575±217 and 732±439 ml respectively in the first two 24-h periods of study. In these starving patients the amount of water released by catabolism of body tissue (probably about 500 ml per day) would be exceeded by insensible water loss (probably about 1000 ml per day) so that there would be a negative water balance of 500–1000 ml per day. Thus, the haemodilution would appear to indicate a fluid shift from the intracellular space to the extracellular space.

The movement of water into and out of cells is determined by osmosis and governed by the relative concentrations of osmotically active particles on either side of the membrane. Any major shift of water out of the cell would be as a consequence of a loss of osmotically active particles, of which potassium is the major constituent.

An increased concentration of potassium in the serum and excretion of potassium in the urine are well-recognized events after surgery and this was observed in these patients. It has been suggested that an

▼Prescribing information

Indications

'Mefoxin' is a broad-spectrum bactericidal antibiotic indicated for the treatment of infections caused by susceptible strains of Gram-positive and Gram-negative pathogens both aerobic and anaerobic.

'Mefoxin' has been clinically effective not only in infections due to antibiotic-sensitive organisms, but also in infections due to organisms resistant to one or more of the following antibacterial agents: penicillin, ampicillin, carbenicillin, tetracyclines, erythromycin, chloramphenicol, cephalosporins, kanamycin, gentamicin, tobramycin, and sulphamethoxazole-trimethoprim.

Many Gram-negative pathogens are resistant to penicillins and cephalosporins through the action of the β-lactamases which are produced by these pathogens. 'Mefoxin' is remarkably stable in the presence of these bacterial β-lactamases, both penicillinases and cephalosporinases. Hence, the clinical efficacy of 'Mefoxin' extends to many infections caused by such pathogens.

'Mefoxin' is indicated for the treatment of the following infections caused by sensitive bacteria:
Peritonitis and other intra-abdominal and intrapelvic infections; female genital tract infections; septicaemia; urinary tract infections; respiratory tract infections; bone and joint infections; and skin and soft-tissue infections.

'Mefoxin' is indicated for adjunctive therapy in the surgical treatment of infections, including abscesses, infection complicating hollow visceral perforations, cutaneous infections, and infections of serous surfaces, whether caused by aerobes, mixed aerobes and anaerobes, or anaerobes.

Microbiology

'Mefoxin' is active *in vitro* against:

Aerobic bacteria

Gram-positive cocci including: Staphylococci: (including coagulase-positive, coagulase-negative, and penicillinase-producing strains); Group A beta-haemolytic streptococci *(Streptococcus pyogenes);* Group B beta-haemolytic streptococci *(Streptococcus agalactiae); Streptococcus pneumoniae (Diplococcus pneumoniae);* other streptococci (except group D streptococci including enterococci, most strains of which are resistant, e.g. *Streptococcus faecalis*). *Gram-negative cocci* including: *Neisseria gonorrhoeae* (including penicillinase-producing strains); *Neisseria meningitidis. Gram-negative rods (facultative anaerobes)* including: *Escherichia coli, Klebsiella pneumoniae;* Klebsiella spp.; *Proteus mirabilis. Proteus* (indole-positive): *Proteus vulgaris; Proteus rettgeri; Proteus morganii; Haemophilus influenzae; Serratia marcescens;* Providencia spp.; Salmonella and Shigella spp.

Anaerobic bacteria

Gram-positive cocci including: Peptococcus spp.; Peptostreptococcus spp.; Micro-aerophilic streptococcus. *Gram-positive rods including: Clostridium perfringens;* Clostridium spp.; Eubacterium spp.; *Propionibacterium acnes. Gram-negative cocci including:* Veillonella spp. *Gram-negative rods including: Bacteroides fragilis; Bacteroides melaninogenicus;* Bacteroides spp. (including both penicillin-susceptible and penicillin-resistant strains); Fusobacterium spp.

'Mefoxin' is active against some strains of the following bacteria: *Acinetobacter calcoaceticus var. anitratum (Herellea vaginicola); Acinetobacter calcoaceticus* var. *lwoffi (Mima polymorpha); Alcaligenes faecalis;* Citrobacter spp. and Flavo-bacterium spp.; Enterobacter spp.

'Mefoxin' is not active against Pseudomonas, most strains of enterococci and many strains of *Enterobacter cloacae.*

Dosage and administration

'Mefoxin' may be administered intravenously or intramuscularly. (See reconstitution directions for each route below.) Dosage and route of administration should be determined by severity of infection, susceptibility of the causative organisms, and condition of the patient.

Therapy may be started while awaiting the results of susceptibility testing.

Dosage: The usual adult dosage is 1 g or 2 g of 'Mefoxin' every eight hours. (See chart.)

In adults with renal insufficiency, an initial loading dose of 1 g or 2 g may be given. After a loading dose, the following recommendations for *maintenance dosage* may be used as a guide.

Usual adult dosage

Type of infection	Dose	Frequency	Total daily dosage
Uncomplicated	1 g	Every 8 hours (occasionally every 6 hours)	3 g (4 g)
Moderately severe or severe	2 g	Every 8 hours (occasionally every 6 hours)	6 g (8 g)
Infections generally needing antibiotics in higher dosage	3 g (2 g)	Every 6 hours (Every 4 hours)	12 g

Maintenance dosage of 'Mefoxin' in adults with reduced renal function

Renal function	Creatinine clearance (ml/min)	Dose	Frequency
Mild impairment	50-30	1-2 g	Every 8-12 hours
Moderate impairment	29-10	1-2 g	Every 12-24 hours
Severe impairment	9-5	0·5-1 g	Every 12-24 hours
Essentially no function	<5	0·5-1 g	Every 24-48 hours

In the patients undergoing haemodialysis, the loading dose of 1 to 2 g should be given after each haemodialysis, and the maintenance dose should be given as indicated in the table above.

Intravenous administration: reconstitute 'Mefoxin' with Water for Injection BP: 1 g is soluble in 2 ml. Although 'Mefoxin' is very soluble, for intravenous use it is preferable to add 10 ml of Water for Injection BP to the 1 g vial or the 2 g vial. Shake to dissolve and then withdraw entire contents of vial into syringe.

For direct intravenous injection, 'Mefoxin' may be slowly injected into

Outstanding clinical benefits

Wide-ranging activity against Gram-negative and Gram-positive pathogens, anaerobes as well as aerobes.

Unusually high resistance to β-lactamase degradation.

Highly active against *Bacteroides fragilis* and strains of *E. coli*, Serratia, Klebsiella spp. and Proteus spp. (including indole positive strains) resistant to other antibacterial agents.

Offers high levels of active antibiotic in the body.

A record of relative safety comparable to the penicillins.

Prime indications include:

- Peritonitis, and other intra-abdominal and intrapelvic infections.
- Female genital tract infections
- Septicaemia
- Skin and soft tissue infections
- Bone and joint infections
- Urinary tract infections
- Respiratory tract infections (e.g. inhalation pneumonia)

Specific clinical profile

'Mefoxin' is exceptionally valuable wherever Gram-negative pathogens and anaerobes are involved in mixed infections. When mixed infections are suspected, therapy may be started while awaiting the results of susceptibility testing.

Mefoxin®

Cefoxitin sodium, MSD

INJECTION

First of the cephamycins

the vein over a period of 3 to 5 minutes or may be given through the tubing when the patient is receiving parenteral solutions.

An intermittent intravenous infusion of 'Mefoxin' may be employed when large amounts of fluid are to be given. However, during infusion of the solution containing 'Mefoxin', it may be advisable temporarily to discontinue administration of any other infusion solution at the same site (by using an appropriate IV infusion set).

A solution of 'Mefoxin' may also be given by continuous intravenous infusion (see below for compatibility and stability).

Intramuscular administration ONLY

Reconstitute 'Mefoxin' 1 g with 2 ml of Water for Injection BP, or 0.5% or 1% lignocaine hydrochloride (without adrenaline) solution. 'Mefoxin' is given by deep injection into a large muscle mass. Avoid injection into a blood vessel.

Compatibility and stability

A solution of 'Mefoxin' in Water for Injection BP may be added to the following solutions: 0.9% Sodium Chloride Injection BP, 5% or 10% Dextrose Injection BP, Dextrose and Sodium Chloride Injection (5%/0.9%, 5%/0.45%, or 4.3%/0.18%), Lactated Ringer's Injection USP, 5% Dextrose in Lactated Ringer's Injection, 5% or 10% invert sugar in water, 10% invert sugar in saline solution, 4.2% Sodium Bicarbonate Injection BP, M/6 Sodium Lactate Injection BP.

'Mefoxin', as constituted to 1 g/10 ml with Water for Injection BP, Water for Injection BP preserved with parabens or benzyl alcohol, 0.9% Sodium Chloride Injection BP or 5% Dextrose Injection BP, maintains satisfactory potency for 24 hours at room temperature, for 96 hours under refrigeration, and for 13 weeks in the frozen state.

'Mefoxin' can be administered concomitantly with such antibiotics as gentamicin, tobramycin, carbenicillin or amikacin. When 'Mefoxin' is administered with another antibiotic, they should not be mixed in the same syringe.

Contra-indications

'Mefoxin' is contra-indicated in persons who have shown hypersensitivity to cefoxitin. In the absence of clinical experience, 'Mefoxin' should not be administered to patients who have shown hypersensitivity to cephalosporins.

Precautions

There is some clinical and laboratory evidence of partial cross-allergenicity between cephamycins and other β-lactam antibiotics, penicillins, and cephalosporins. Severe reactions (including anaphylaxis) have been reported with most β-lactam antibiotics.

Before therapy with 'Mefoxin', careful inquiry should be made concerning previous hypersensitivity reactions to β-lactam antibiotics. 'Mefoxin' should be given cautiously to penicillin-allergic patients.

Any patient who has demonstrated some form of allergy, particularly to drugs, should receive antibiotics cautiously. If an allergic reaction to 'Mefoxin' occurs, the drug should be discontinued.

The total daily dosage should be reduced when 'Mefoxin' is administered to patients with transient or persistent reduction of urinary output due to renal insufficiency (see 'Dosage and administration') because high and prolonged serum antibiotic concentrations can occur from usual doses.

Interference with laboratory tests

A false-positive reaction to glucose in the urine may occur with reducing substances but not with the use of specific glucose oxidase methods.

Use in pregnancy

Use of the drug in women of childbearing potential requires that the anticipated benefits be weighed against possible hazards. Reproductive and teratogenic studies have been performed in mice and rats and have revealed no evidence of impaired fertility or harm to the foetus due to 'Mefoxin'. There are no controlled studies with 'Mefoxin' in pregnant women.

Nursing mothers

'Mefoxin' is excreted in human milk.

Infants and children

Pending the outcome of clinical trials in progress, the conditions for use of 'Mefoxin' in infants and children remain to be defined.

Side effects

'Mefoxin' is generally well tolerated. Side effects rarely require stopping treatment and usually have been mild and transient.

Local reactions

Thrombophlebitis has occurred with intravenous administration. Pain induration and tenderness after intramuscular injections have been reported.

Allergic

Maculopapular rash, urticaria, pruritus, eosinophilia, fever and other allergic reactions have been noted rarely.

Gastro-intestinal

Diarrhoea has been reported rarely.

Blood

Transient leucopenia and neutropenia have been reported. Some individuals, particularly those with azotaemia, may develop positive direct Coombs tests during therapy with 'Mefoxin'.

Liver function

Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase have been reported rarely.

Kidney

Elevations in serum creatinine and/or blood urea levels have been observed. The role of 'Mefoxin' in changes in renal function tests is difficult to assess, since factors predisposing to pre-renal azotaemia or to impaired renal function usually have been present.

Presentation

In vials containing 1 g or 2 g of cefoxitin as the sodium salt. Each gram of cefoxitin contains approximately [illegible] mg ([illegible]) of sodium.

Product licence numbers: 1 g 0025/0130, 2 g [illegible]

Product authorisation numbers: 1 g PA 35/42/1, 2 g PA 35/42/2

Issued October 1978

Additional information is available to the medical profession on request.

Basic NHS cost is £[illegible] for the 1 g vial, and £[illegible] for the 2 g vial.

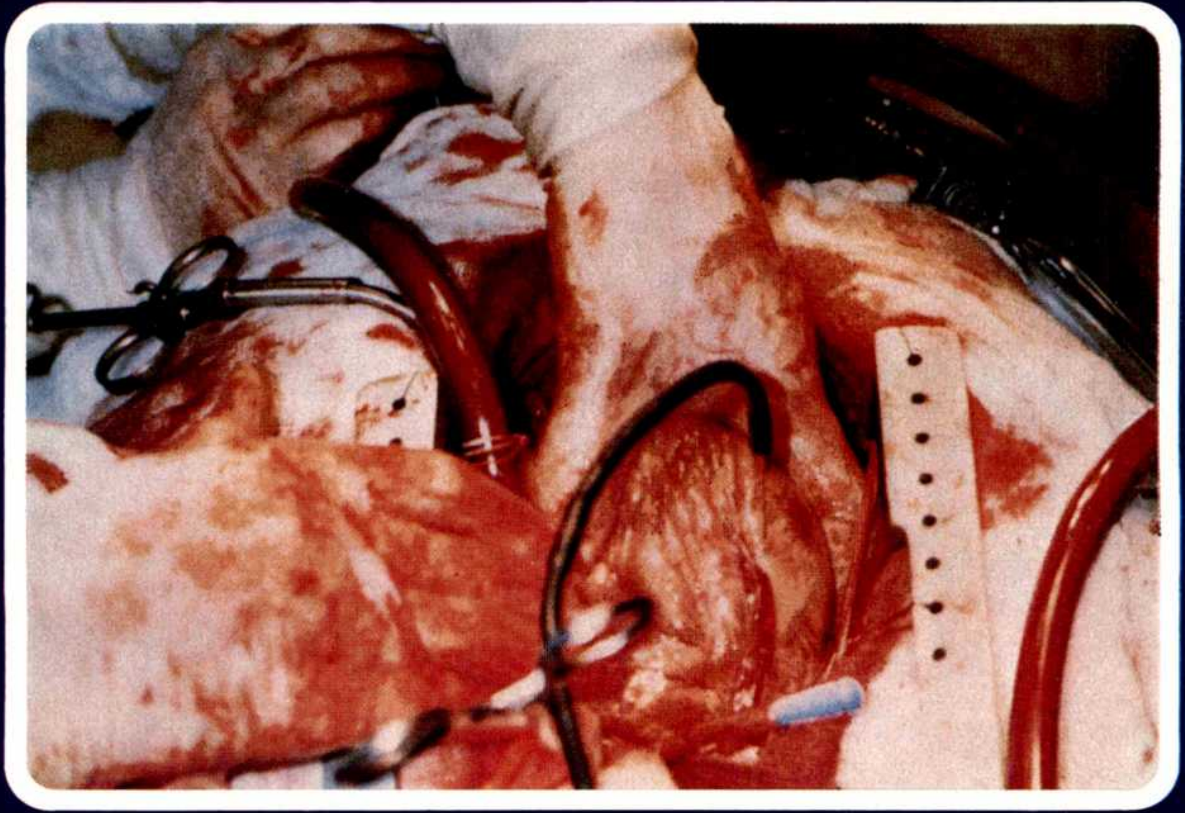
Magnapen

ampicillin/flucloxacillin



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

Prescribing Information

Magnapen Capsules: Black and turquoise capsules overprinted "Magnapen" containing 250mg ampicillin as Ampicillin Trihydrate B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Magnapen Syrup: Bottles containing powder for the preparation of 100ml suspension. When reconstituted each 5ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. with 125mg flucloxacillin as flucloxacillin sodium.
Magnapen Vials: Each vial contains 250mg ampicillin as Ampicillin Sodium B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Uses: Severe infections. Post-operative chest and wound infections. Prophylaxis in major surgery.

Dosage: Adult: 1 capsule or 10ml syrup, or 1 vial qid. Children: 2-10 years, ½ adult dose. Under 2 years, ¼ adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL 0038/5001, 5009.
Contra-indications: Penicillin hypersensitivity, ocular administration.
Side-effects: As with other penicillins. An erythematous rash may occasionally occur, as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported, it is advisable to discontinue treatment.
Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product literature before using with intravenous fluids.

Basic N.H.S. Prices: (correct at time of printing, Feb.79).
Capsules: 500mg, £18.06 (100 capsule pack).
Syrup: 250 mg per 5 ml, £3.18 (100ml).
Vials: 500mg, £7.45 (10 vials).

Magnapen is available to hospitals on regional contract dependent upon estimated usage.

Further information on Magnapen is available on request to the company.

Magnapen, BRL and the Company logo are registered trade marks.

increase in cell membrane permeability with subsequent quantitative and qualitative changes in the normal distribution of extracellular and intracellular electrolytes is the initial change in the sequence of events that constitute the metabolic response to injury (Flear, 1973). This increase in cell membrane permeability was attributed to impaired tissue perfusion and hypoxia but the decrease in tissue oxygenation following routine surgery is comparatively small (Nunn, 1965). The changes in the extracellular fluid volume after surgery have been investigated in the past but the results have been contradictory (Flear, 1970). The substances used to measure extracellular fluid volume may enter the cells owing to a change in membrane permeability (Breckenridge et al., 1970) and give rise to erroneous conclusions. However, haemodilution was not the sole cause of postoperative hypophosphataemia as the extent of the reduction in serum inorganic phosphorus concentration, packed cell volume and serum albumin concentration showed quantitative differences. Nevertheless, the extent of the fall in serum inorganic phosphorus in the group receiving phosphorus supplementation does not suggest that deficient intake was a major factor. A further potential mechanism for loss of extracellular phosphorus is passage into the cell but this is most unlikely in this setting as all the evidence suggests that the opposite occurs following surgery (Cuthbertson, 1930).

It is concluded that the fall in the concentration of serum inorganic phosphorus following these elective operations was largely the result of haemodilution. However, the falls in concentration of serum inorganic phosphorus, and of red blood cell 2,3 diphosphoglycerate and adenosine triphosphate were small and self-correcting and there is no indication for routine postoperative phosphorus supplementation in uncomplicated elective surgery.

The effect of aspirin on the fibrinolytic activity of gastric juice

T. E. O'BRIEN, HELEN HADLEY AND M. H. IRVING*

SUMMARY

Fibrinolytic activity in the gastric juice of normal subjects has been studied by a double-blind cross-over technique comparing the effect of placebo and pentagastrin against aspirin and pentagastrin. Aspirin effectively produced a gastritis and pure fibrinolytic activity was detected in the gastric juice, but the number of samples showing pure fibrinolytic activity did not differ between the two groups. In both the placebo and the aspirin groups the presence of a protease active at neutral pH and capable of dissolving fibrin is confirmed. Aspirin is unlikely to cause gastric bleeding by increasing local fibrinolytic activity within the stomach. The model, so constructed, is not sensitive enough to be of value in investigating further the role of gastric fibrinolytic activity in gastric haemorrhage.

FIBRINOLYTIC activators occur in many tissues (Astrup, 1966). Under normal circumstances the fibrinolytic system subserves the useful function of removing fibrinous deposits and maintaining the patency of small ducts and blood vessels. When such tissues are damaged, however, activation of the fibrinolytic system may potentiate bleeding, as has been demonstrated in the uterus and prostate (McNichol et al., 1961; Rybo, 1966).

Two studies (Cox et al., 1967; Nilsson et al., 1975) have implicated gastric fibrinolytic activity as an aetiological factor in gastroduodenal haemorrhage, and the results of two controlled trials in which an anti-fibrinolytic agent was used to treat patients with upper gastrointestinal haemorrhage would seem to confirm this (Cormack et al., 1973; Biggs et al., 1976). Gastric juice has been shown to be capable of dissolving fibrin and fibrin clots under certain circumstances (Oleson, 1972). This fact has obvious implications in patients who are actively bleeding from the stomach.

The aim of the present study was to ascertain whether it is possible to contruct a model in the human subject, to study fibrinolytic activity in gastric juice and to see whether increased local fibrinolysis might account for the known tendency for gastric bleeding to occur after the ingestion of salicylate.

Patients and methods

A double-blind cross-over study was performed on 10 healthy volunteer subjects who underwent two standard pentagastrin tests following the oral administration of aspirin and a placebo (lactose).

Capsules, containing 300 mg of either aspirin (acetylsalicylic acid) or lactose, were made by the hospital pharmacist. Six capsules were placed into each of two bottles labelled treatment A and treatment B. Only the pharmacist knew what each bottle contained. Cards giving instructions on the order in which the treatments were to be taken were placed in envelopes and randomly given to each subject. The volunteers were instructed to eat nothing after 12 midnight on the day of the test. At 12 midnight the volunteer swallowed three capsules as instructed on the card. The three remaining capsules were ingested 1–1½ h before the start of the pentagastrin test. Thus, a total of 1·8 g of compound was taken over a period of 8–9 h on an empty stomach. A standard pentagastrin test was then performed in the usual manner. The following samples of gastric juice were collected and examined for fibrinolytic activity: the resting gastric juice, basal samples taken at 30 min and 60 min; samples taken at 30 min and 60 min after the subcutaneous injection of pentagastrin (0·6 μg/kg).

The pH and the presence of blood and/or bile were noted on all the samples obtained.

After an interval of at least 2 weeks the test was repeated, the subject taking the remaining compound in a similar fashion.

Fibrinolytic activity in the gastric juice was assessed using a fibrin plate technique, the plates being prepared according to the methods of Astrup and Mullertz (1952) and Lassen (1953). In order to characterize the type of fibrinolytic activity obtained, plates were also prepared incorporating EACA and Trasylol.

The area of lysis obtained was determined by measuring the diameter of the lytic zone in two directions at right-angles to each other and multiplying the two measurements. An illuminated transparent plastic grid marked in 1-mm squares was used to facilitate the accurate measurement of the lytic area.

Fibrinogen from the same batch sample was used in the performance of all tests.

On completion of the study the code was broken and the results analysed.

Results

Ten subjects were studied, 5 male and 5 female, with a mean age of 28·9 years (range 20–42 years). Aspirin proved to be an effective gastric irritant, 40 per cent of the pre-pentagastrin and 53 per cent of the post-pentagastrin samples being frankly bloodstained, whereas after the placebo only 4 per cent of the pre-pentagastrin and 27 per cent of the post-pentagastrin samples were bloodstained.

Strict criteria have been adopted for defining pure fibrinolytic activity. Lysis occurring on standard and heated plates, but which was suppressed by EACA and Trasylol, was interpreted as pure fibrinolysis, except when the lysis on the heated plate was equal to or greater than that occurring on the standard plate. In this latter instance this was interpreted as non-specific proteolysis. Lysis occurring on all plates indicated non-specific proteolysis.

The patterns of activity obtained are shown in *Tables I* and *II*.

Pure fibrinolytic activity was seen in both groups, but there was no difference between the two groups in the numbers of samples showing this activity. Thus in the placebo group 6 out of 30 (20 per cent) of pre-pentagastrin samples and 4 out of 20 (20 per cent) post-pentagastrin samples showed pure activity, and in the aspirin group 7 out of 30 (23·3 per cent) pre-pentagastrin and 3 out of 20 (15 per cent) post-pentagastrin samples showed pure activity.

The patterns of lysis obtained in those samples showing pure fibrinolytic activity are shown in *Table III*. In addition, only 4 out of the 20 samples showing

pure fibrinolytic activity were bloodstained. Also, of the 20 samples showing fibrinolytic activity, 13 had a gastric juice pH of 3·0 or less.

Discussion

It is a common clinical observation that in cases of upper gastrointestinal haemorrhage the bleeding is often intermittent in character. One possible explanation for this is a sequence of clot formation leading to cessation of bleeding, followed by spontaneous clot lysis leading to rebleeding. Several enzymes are capable of dissolving fibrin; among these are trypsin and other pancreatic proteases. Pepsin, in the presence of hydrochloric acid, has been shown to cause lysis of the fibrin in fibrin plates although pepsin alone is without effect (Cox et al., 1967). The demonstration by Nilsson (1975) of increased fibrinolytic activity in the gastric juice of patients bleeding from erosive gastroduodenitis, and their subsequent improvement following the administration of an antifibrinolytic agent, has important implications. The question this finding raises is: 'Would examination of the gastric juice of patients with upper gastrointestinal bleeding be of value in predicting which of these patients would benefit from anti-fibrinolytic therapy?' The present study has attempted to construct a model to investigate this possibility. The results show that in a certain proportion of cases gastric juice in normal subjects without gastric haemorrhage may exhibit pure fibrinolytic activity. The administration of a known gastric irritant, aspirin, did not increase the numbers of samples of gastric juice showing pure fibrinolytic activity.

Table I: PATTERNS OF LYSIS OBTAINED IN THE 10 SUBJECTS IN THE PLACEBO GROUP

	Pre-pentagastrin			Post-pentagastrin	
Subject	Sample 1	Sample 2	Sample 3	Sample 4	Sample 5
1	0	1	2	0	1

Since the original report of Douthwaite and Lintott (1938), there has been increasing evidence to suggest an association between aspirin ingestion and the development of acute gastric mucosal lesions. The mechanisms of gastric haemorrhage after salicylate ingestion remain obscure. It is known, however, that aspirin ingestion causes exfoliation of gastric mucosal cells (Croft, 1963) and multiple erosions after repeated small doses (Croft and Wood, 1967). The amount of bleeding after aspirin ingestion is related to the particle size of the aspirin (Győry and Stiel, 1968), and in this study coarse aspirin (large particle size) was used. Aspirin is also known to affect platelet function, which may, of course, be relevant to any bleeding tendency (O'Brien, 1968). The occurrence of gastric bleeding is also related to gastric acidity—the higher the acidity the greater is the amount of bleeding (Davison et al., 1966; Croft and Wood, 1967)—and in this study the number of samples of gastric juice showing heavy bloodstaining increased after the administration of pentagastrin. As endoscopy was not performed on the subjects studied, it is not possible to be absolutely sure that the aspirin did in fact cause gastric erosions and a gastritis, and the evidence that this occurred rests only with the finding of increased numbers of samples of heavily bloodstained gastric juice in the aspirin-treated group. However, it is possible that this bloodstaining might simply reflect increased permeability of the gastric mucosa, as aspirin is known to cause changes in this (Smith et al., 1971). The purpose of administering pentagastrin was both to stimulate acid secretion, in the hope of enhancing the effect of the aspirin, and also to increase gastric mucosal blood flow (Thompson, 1969). Aspirin is known to effect changes in the fibrinolytic system of the blood (Menon, 1970; Moray, 1977), but the results in this study suggest that it does not alter fibrinolytic activity in gastric juice. The finding of 'pure' fibrinolytic activity in the gastric juice of normal subjects was surprising, as one would expect that any plasminogen activator present within the gastric lumen would be destroyed by gastric acid.

The most common action of gastric juice on fibrin plates is either no lysis at all or non-specific proteolysis. In this study the pH of the gastric juice was adjusted to 7·0 before the juice was placed on the plates. At this pH pepsin has no activity on fibrin plates; thus, the lysis obtained was probably not due to pepsin. In many samples showing large areas of non-specific proteolysis the juice was bile-stained, evidence of duodenal reflux. Almost certainly the lysis of fibrin in these samples was due to pancreatic proteases, although bile is known to contain activators of plasminogen (Oshiba et al., 1969). However, not all the samples causing proteolysis were bile-stained. Taylor (1959) has identified a protease in gastric mucosal tissue which is active at neutral pH and Eras et al. (1970), using histochemical techniques, also found proteolytic activity related to the epithelial surface of the gastric mucosa which was not inhibited by EACA or heat. The results of this study also serve to confirm the presence of an enzyme capable of dissolving fibrin which is active at pH 7·0. The origin of the fibrinolytic activity in the gastric juice remains open to conjecture. The studies of Cox et al. (1967, 1969) and of Thompson (1974) have demonstrated that the gastric venous blood may exhibit marked fibrinolytic activity. In our study the fibrinolytic activity demonstrated in the gastric juice in all but 7 of the samples was that of plasminogen activator. It is possible that the origin of this activator was the rich mucosal and submucosal capillary plexuses. However, the fibrinolytic activity in the gastric juice was not increased after inducing gastric hyperaemia with pentagastrin in either the aspirin or placebo groups. It is interesting to note also that the majority of the samples exhibiting pure fibrinolytic activity were not bloodstained, indicating that the presence of blood in the stomach is not necessarily associated with the findings of fibrinolytic activity in the gastric aspirate. The other possible source of the plasminogen activator activity is swallowed saliva, saliva having been shown to contain substantial amounts of plasminogen activator (Albrechtsen and Thaysen, 1955). The presence of an oral or nasogastric tube may induce the subject to swallow more frequently. It is of interest also to find that in 13 out of the 20 samples of gastric juice showing pure fibrinolytic activity the pH was 3·0 or less, showing that activator is not necessarily destroyed at once in an acid environment.

In conclusion, therefore, gastric juice may exhibit pure fibrinolytic activity in the absence of gastric bleeding. The administration of aspirin did not induce increased fibrinolytic activity in gastric juice even after giving pentagastrin, and this model so constructed is unlikely to be of use in the study of the fibrinolytic activity of gastric juice. The origin of the plasminogen activator present in the samples showing pure fibrinolytic activity remains open to doubt. However, the study does demonstrate that gastric juice is capable of dissolving fibrin even at neutral pH, and although this is not fibrinolysis in the accepted sense, it offers a possible explanation as to the cause of the intermittent nature of gastroduodenal haemorrhage.

Technical index

Reagents

Thrombin: Bovine thrombin (Leo Laboratories) 5000 NIH units. 5 ml of N-saline and 5 ml of glycerol were added to each ampoule of thrombin, giving a concentration of 500 NIH units/ml. This was stored at −20 °C until ready for use. When ready, the thrombin solution was thawed and diluted 1 : 9 with 0·9 per cent NaCl giving a final concentration of 50 NIH units/ml.

Phosphate buffer: pH 7·3.

Epsilon-amino caproic acid: Epsikapron (AB Kabi, Stockholm). A 1 per cent solution was prepared in phosphate buffer.

Fibrinogen: Lyophilized fibrinogen (grade L) (AB Kabi, Stockholm). Reconstituted as a 1 per cent solution, divided into 2-ml aliquots and stored at −20 °C.

Streptokinase (AB Kabi, Stockholm). Supplied as lyophilized powder, 100 000 i.u. One vial (100 000 units) was dissolved in 50 ml 0·9 per cent NaCl, divided into 2-ml aliquots and stored at −20 °C until required.

Aprotinin: Trasylol, 1000 units/ml (Sigma).

The modified plates were prepared as follows:

EACA plate

8 ml of a 1 per cent solution of EACA in phosphate buffer were added to 2 ml of fibrinogen, the contents mixed and 9 ml of the mixture poured into the appropriate Petri dish. The solution was clotted with 0·1 ml thrombin (50 NIH units/ml).

Trasylol plate

6 ml of phosphate buffer and 2 ml of Trasylol (1000 units/ml) were added to 2 ml of fibrinogen, the contents mixed and 9 ml of the mixture poured into the Petri dishes. The solution was clotted with 0·1 ml thrombin.

0·03 ml of a solution containing 2000 units/ml of streptokinase were added to the heated plates as control.

Preparation of samples

After collection of the samples into small plastic containers, they were placed in a vacuum flask containing melting ice and transported to the laboratory without delay. The pH of each sample was adjusted to 7·0 and then 0 03 ml of the juice were immediately placed on the fibrin plates. The plates were then incubated for 18 h at 37 °C, after which time the areas of lysis obtained were measured using an illuminated transparent plastic grid.

Chronic abdominal pain: a surgical or psychiatric symptom?

C. R. J. WOODHOUSE AND S. BOCKNER*

SUMMARY

A prospective investigation of chronic, non-specific abdominal pain in 20 patients is reported. The cause was found to be psychiatric in 8 (40 per cent), while a surgical cause was found in only 3 (15 per cent). Four had irritable colon (20 per cent) and no diagnosis was made in 5 (25 per cent). It is suggested that such pain is more often a psychiatric than a surgical symptom and therefore a psychiatric consultation should be a routine part of the investigation.

CHRONIC abdominal pain is one of the commoner presenting symptoms in surgical outpatient clinics. In many cases the pain is non-specific, the history does not suggest disease in any particular organ and physical signs are few or absent. Extensive investigation fails to show a surgical cause and the patients often remain undiagnosed. We have used a combined surgical and psychiatric approach to try to establish a diagnosis in a group of such patients.

Patients and methods

We investigated all patients over 18 years of age presenting with a history of abdominal pain for more than 2 years and whose symptoms did not indicate a specific disease. A full history was taken with particular reference to the duration of the pain, periodicity, precipitating factors and associated symptoms. They were specifically asked about recurrent pains in childhood and at other times. If they had had abdominal or pelvic surgery the indications for it were established.

All had a 'ward test' of urine (Haemocombistix, Ames Ltd), urine culture and a full blood count. Other investigations were carried out according to the clinical indications (investigations are shown in *Table I*). If there was no somatic diagnosis, a full psychiatric assessment was made.

Results

Twenty-eight patients were seen between April and December 1977. Eight failed to complete the course of investigation and were lost to follow-up. Twenty patients are available for analysis. A definite diagnosis was made in 15 patients: 3 had a 'surgical' disease, 8 a psychiatric disease and 4 had an irritable colon. In the remaining 5 patients no diagnosis was made. The results are summarized in *Table II*.

Surgical causes

There were 3 patients in this group (15 per cent). All were over 60 years old. Their symptoms were not typical of their disease, but were relieved by conventional treatment for the identified lesion. The first patient was a woman of 76 years with a long history of pain in the epigastrium and both iliac fossas. She was eventually found to have diverticulosis coli with an irregular stricture of the upper sigmoid. At operation the stricture was found to be due to inflammatory changes in the bowel wall. Reilly's myotomy was performed and she remains free of symptoms 14 months later.

The second patient was correctly diagnosed as having gallstones only when seen during an attack of acute cholecystitis. The third woman had longstanding collapse of 3 thoracic vertebrae causing root pain, which was only diagnosed, after prolonged investigation, when the crucial past history was elicited.

Psychiatric causes

A psychiatric diagnosis was made in 8 cases (40 per cent). Five had chronic anxiety states, 2 had obsessional states and 1 had endogenous depression.

There were 6 women and 2 men in this group, with an average age of 32 years (range 25–44). Pain had been present for between 2 and 17 years but 3 patients could give no definite duration. None remembered having pain before puberty. All were vague about

Table I: INVESTIGATIONS UNDERTAKEN IN 20 PATIENTS WITH CHRONIC, NON-SPECIFIC ABDOMINAL PAIN

Investigation	No. of cases
Barium enema and sigmoidoscopy	16
Barium meal	15
Intravenous urogram	13
Oral cholecystogram	8
Liver function tests	3
Thyroid function tests	2
Spinal X-rays	2
Intravenous cholangiogram	1
Serum amylase	1
Lactose tolerance test	1

Table II: DIAGNOSIS OF 20 PATIENTS WITH CHRONIC, NON-SPECIFIC ABDOMINAL PAIN

Diagnosis	No. of cases	
Surgical causes	3	
Inflammatory stricture of colon		1
Gallstones		1
Collapsed thoracic vertebrae		1
Psychiatric causes	8	
Chronic anxiety states		5
Obsessional states		2
Endogenous depression		1
Irritable colon	4	
Undiagnosed	5	

Table III: SYMPTOMS ASSOCIATED WITH ABDOMINAL PAIN IN 8 PSYCHIATRIC CASES

Symptom	No. of cases
Bowel disturbance	3*
Worsening of pain with stress	3
Anorexia	2
Abdominal swelling	2
Vomiting	2
Weight loss (only during pain)	1
Nausea	1

their symptoms, admitting, for example, to intermittent pain, yet only 2 having an accurate idea of its periodicity. Associated symptoms were scarce, as *Table III* shows.

Physical signs were unhelpful. The patients all looked well and none was obese. Four had tenderness in the right iliac fossa, 2 with a poorly defined mass (these 2 were submitted to elective appendicectomy, 1 was unchanged after the operation and 1 was worse). Further consultation eventually established the correct diagnosis.

Conventional treatment was given using psychotherapy and drugs as required; 5 out of the 8 have improved and have had no recurrence of their pain. The follow-up of these patients now ranges between 8 and 15 months and none has developed an organic disease.

Irritable colon

In 4 patients (20 per cent) a diagnosis of irritable colon was made. All had lower abdominal pain with alteration of bowel habit; 3 had constipation and 1 had variable constipation and diarrhoea. In spite of at least 3 years of history, all remained in good general health without weight loss. Only 1 patient associated his pain with stress and none had distinct psychiatric disease.

Two patients had tender descending colons and 1 had minimal reddening of the rectal mucosa, which was found to be normal on histology of multiple biopsies. All 4 had normal barium enema examinations and extensive investigation failed to show another cause for the symptoms. The patients were treated with bulk laxative (ispaghula husk) with complete relief of symptoms and they all remain well after 11–15 months' follow-up.

Undiagnosed group

In 2 men, aged 53 and 54 years respectively, the symptoms were considered sufficiently severe to warrant laparotomy: no pathology was found, but 1 had a normal appendix removed. Both remain free of abdominal pain after 8 and 14 months of follow-up. Three other patients remain undiagnosed and continue to have pain.

Discussion

Chronic non-specific abdominal pain is a notoriously difficult symptom to diagnose. In one retrospective review of patients whose pain 'failed to conform to specific patterns' only 10 of 76 were diagnosed. The younger the patient and the greater the duration of symptoms, the more unlikely diagnosis became (Sarfeh, 1976). Gynaecological practice reveals similar experience when only 14 out of 49 patients with pain of 'chronic non-specific type' were found to have an abnormality on laparoscopy (Ferguson, 1974). Even in acute episodes of abdominal pain diagnosis has been shown to be possible in less than half of 1000 cases (Brewer et al., 1976).

Abdominal pain has been known as a symptom of emotional disorders since ancient Greek times; hence the term 'hypochondriasis', meaning 'below the costal cartilages', coined by Hippocrates. In the language of symptoms, the unhappy patient is literally 'bellyaching' about his problems. Anxiety states, obsessional states and endogenous depressions are the commonest psychiatric causes for abdominal pain (Gomez and Dally, 1977). Recently the role of psychiatric factors in the aetiology of chronic abdominal pain has been neglected, though such factors are well established in children (Apley and Naish, 1958; Dodge, 1976). Although it has been suggested that little bellyachers grow up into big bellyachers (Editorial, 1975), such histories were not given by our patients.

In 8 of our 20 patients (40 per cent) psychiatric causes for chronic abdominal pain were found and over half of them have made a good response to treatment. A further 4 had irritable colon, and it has been shown that in this condition disturbed colonic motility can be mediated by emotional upsets (Chaudhary and Truelove, 1961). The histories of our patients were as long as 17 years, and yet their general health remained good. Nevertheless, there is a clear possibility that they may yet develop an organic disease, and a change of symptoms or relapse while under psychiatric treatment would be an indication for further investigation.

Only rarely did we find that this type of pain had a 'surgical' cause and only when the patient was over 60 years old. We now accept that where a patient is under 40 years old, has few symptoms other than pain and no physical signs, it is sufficient to test the urine, do a full blood count and one radiological investigation. Within this framework the patient is shown that his complaint is being taken seriously and a psychiatric consultation is accepted. In this series no organic diagnosis would have been missed with this programme. We regard the psychiatric assessment as part of the routine work-up and positive psychiatric features do not preclude further investigation.

Our experience with this difficult group of patients is that diagnosis is possible in 75 per cent of cases. Chronic, non-specific abdominal pain is more often a psychiatric than a surgical symptom and a combined approach by both specialties is helpful.

Acknowledgement

We are most grateful to Mr J. M. Beaugie for permission to report on his patients.

Interstitial emphysema of the stomach

A. R. TURNBULL AND R. C. MICHELL*

SUMMARY

A case of interstitial emphysema of the stomach is reported and the possible aetiological factors involved are discussed.

THE presence of gas within the wall of the stomach is rare and probably unfamiliar to many surgeons. The condition may occur as a result of a phlegmonous gastritis due to gas-forming organisms, but it may also occur in non-infective conditions.

Case report

An 85-year-old diabetic woman presented as an emergency with a 1-week history of epigastric pain and vomiting. Two months previously she had been admitted with a haematemesis and melaena, and a barium meal examination had shown a duodenal ulcer with pyloric narrowing. On that occasion she had been treated conservatively with cimetidine and her condition had improved sufficiently to allow her to undergo a total hip replacement. However, a week following this procedure she had developed epigastric pain which radiated retrosternally. This had been associated with profuse vomiting and she had had further melaena. On this present admission the patient was clinically dehydrated but the temperature was normal, the pulse rate was 84/min and she was normotensive. There was epigastric tenderness and a succussion splash could be elicited. Investigations showed a haemoglobin of 15·8 g/dl and a white blood cell count of $24{\cdot}4\times10^9$/l. The blood urea was 28·0 mmol/l and the sodium was 119 mmol/l, potassium 3·8 mmol/l and bicarbonate 33 mmol/l. The blood glucose was 14·0 mmol/l. Abdominal radiographs (*Fig.* 1) showed a large stomach outlined by a linear gas shadow. The patient was rehydrated and her biochemistry corrected. Gastric lavage was carried out and she came to laparotomy 2 days later. At operation she was found to have a large stomach with pyloric stenosis secondary to duodenal ulceration. Gallstones were also present. There was crepitus of the stomach wall similar to subcutaneous surgical emphysema. A truncal vagotomy and Heineke–Mickulicz pyloroplasty was performed and the gallbladder removed. The cut surface of the stomach appeared normal macroscopically and there was no evidence of inflammation. The patient made a satisfactory postoperative recovery from this procedure, and has remained well since.

Discussion

Gas may be seen in the wall of a hollow viscus, such as the stomach, in various situations: these have been classified into three groups by Colquohoun (1965). It may result from infection with gas-forming organisms, it may occur in cystic pneumatosis intestinalis and it may present as interstitial emphysema associated with outlet obstruction.

When the condition is due to infection with gas-forming organisms it is known as emphysematous gastritis. This has been reported following the ingestion of corrosives, gastric infarction or gastroduodenal surgery (Meyers and Parker, 1967). The patient becomes extremely ill with signs of overwhelming infection and surgery has little effect on the outcome, which is invariably fatal. Abdominal radiographs show a contracted stomach with numerous small gas bubbles within the wall.

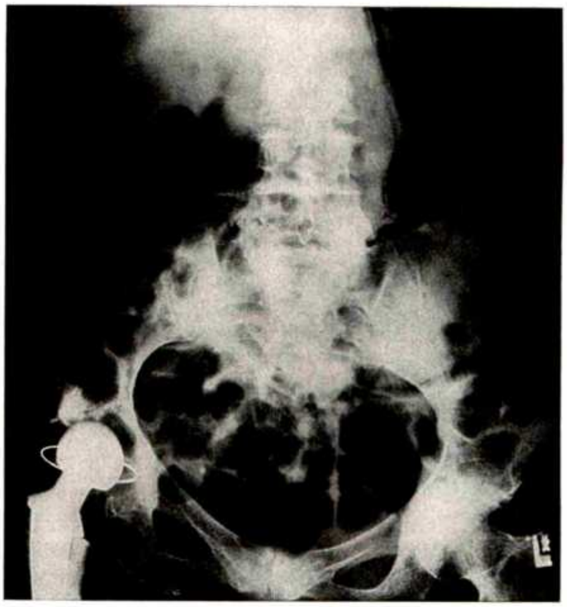

Fig. 1. Plain abdominal radiograph showing a large stomach outlined by a linear gas shadow.

Cystic pneumatosis intestinalis is more commonly seen in the colon and rarely affects the stomach. However, it has been described in patients with chronic pulmonary disease and pyloric obstruction (Colquohoun, 1965). The radiographic appearances are similar to those of emphysematous gastritis, but the stomach is not contracted. The two conditions can be differentiated clinically.

Interstitial emphysema of the stomach is associated with outlet obstruction and has been described secondary to duodenal obstruction from impacted gallstones (Schorr and Marcus, 1962), and secondary to carcinoma of the pyloric antrum (Ward, 1960). The condition may result from raised intraluminal pressure caused by vomiting. In this condition the abdominal radiograph shows an overdistended stomach outlined by a submucosal gas shadow or stripe.

The clinical picture and radiographic appearances in the case described here are those of interstitial emphysema of the stomach secondary to pyloric stenosis from duodenal ulceration. Although the white blood cell count was significantly raised preoperatively, there was no evidence of a severe or overwhelming infection to suggest that the patient had emphysematous gastritis. At operation there was no sign of an inflammatory process, but in retrospect it would have been of interest to have taken swabs for bacterial examination and a biopsy of the stomach wall for histology. In addition, the outcome was favourable, whereas emphysematous gastritis is invariably fatal. Cystic pneumatosis intestinalis has

been described with pyloric obstruction but the radiographs of the patient showed an overdistended stomach outlined by a linear gas shadow or stripe. This is the characteristic appearance of interstitial emphysema rather than cystic pneumatosis, where there are numerous gas bubbles within the wall of the viscus.

Surgical Research Society

The Winter Meeting of the Surgical Research Society was held at the Royal Free Hospital and Medical School on 4 and 5 January 1979 with Professor R. B. Duthie (President of the Surgical Research Society) in the chair. The following papers were presented.

1. Intravenous feeding in cancer patients receiving radiotherapy

D. VALERIO, A. MALCOLM and G. L. BLACKBURN, *Nutrition Metabolic Clinic, Cancer Research Institute, New England Deaconess Hospital, Boston, Massachusetts*

Malnutrition is a common feature of cancer (Schein et al., 1975) while intravenous feeding has been proposed as a significant support to cancer therapy (Copeland et al., 1977). A randomized prospective trial was designed to investigate the role of intravenous feeding in patients, who were planned to receive 4000 rad minimum to the abdomen or pelvis. Twenty patients entered the study: 11 were randomized to intravenous feeding receiving 40–45 kcal kg^{-1} d^{-1}, and 9 control subjects were allowed to eat normally. A nutritional assessment was made before and at the end of radiotherapy, with measurement of triceps skinfold, arm muscle circumference, creatinine height index, albumin, transferrin, lymphocyte count, reticulocyte count and delayed hypersensitivity skin testing.

The patients receiving intravenous feeding had more advanced cancer, a lower initial serum albumin and a greater pre-treatment weight loss than the controls. In the group receiving feeding an average weight gain of 2·1 kg occurred ($P<0{\cdot}05$) while the controls maintained their weight. Albumin levels fell in both groups, while a significant rise in transferrin level ($P<0{\cdot}01$) and reticulocyte count ($P<0{\cdot}01$) occurred in the feeding group and transferrin levels fell in the control group. In the feeding group 5 patients had a 50 per cent or more reduction in tumour mass compared with 3 in the control group. The catheter-related sepsis rate was zero.

These preliminary data suggest that intravenous feeding may play an important supportive role and may be given safely to the nutrionally depleted cancer host.

2. The continent ileostomy reservoir: a comparative study of the competence of five valve designs

B. CRANLEY and S. T. D. MCKELVEY, *Department of Surgery, Queen's University, Belfast*

Valve extrusion is one of the most troublesome problems associated with the continent ileostomy reservoir (Goligher and Lintott, 1975). We have investigated the competence of three valves in current clinical use and have included two of our own modifications for comparison as follows:

I. Kock valve with serosal diathermy ($n=6$).

II. Kock valve with seromuscular diathermy (Madigan, 1976) ($n=6$).

III. Kock valve with offsetting of the two mesenteric leaves to allow suturing between them (Kock, 1976) ($n=6$).

IV. The gut is transected. A nipple is fashioned in the distal segment and reinserted into the proximal segment ($n=6$).

V. Kock valve with mesentery excluded from the intussusception ($n=5$).

Each valve was made in an isolated loop of dog's ileum. After 10 weeks all valves were subjected to incremental pressures and leakage pressure was recorded.

The performance of types II, III, IV and V was compared with that of the standard valve (type I) (Table).

Statistically significant differences in performance were observed between type I and the other valves. Seromuscular diathermy and offsetting the mesentery improves valve function. Excluding mesentery from the intussusception prevents extrusion at the mesenteric aspect without producing ischaemia. This design merits further investigation.

3. Results of conservative management of patients with acute traumatic intradural haematomas

S. GALBRAITH, G. TEASDALE and B. JENNETT, *Department of Neurosurgery, Institute of Neurological Sciences, Glasgow*

Since the introduction of the CT scanner it has become apparent that intracranial haematomas can be present in the absence of clinical deterioration and in situations in which previously they would not have been suspected. Because the natural history of these haematomas was not known, we have investigated how often surgery was required and whether or not this could be predicted.

Eighteen patients with an acute traumatic intradural haematoma demonstrated by CT scanning and in whom there was no neurological deterioration were investigated. Patients were closely observed and intracranial pressure was monitored with an intraventricular catheter. Surgery was performed if there was clinical deterioration or if there was no improvement.

Seven patients required an operation and, of these, 4 made a good recovery, but 3 died. Of those managed without an operation, 10 made a good recovery and 1 remains severely disabled. Patients who were not in a coma and had no midline shift did not require surgery. However, apart from this, age, midline shift, intracranial pressure and level of responsiveness were unhelpful in predicting the need for surgery.

In this series only 39 per cent of patients eventually required an operation. Yet, because of the lack of certainty of their clinical course, and the difficulties encountered in adopting a conservative approach, we currently advise surgery in all patients except those with no midline shift and who are not in a coma.

4. The surface ultrastructure of normal and ectatic human breast ducts

R. E. MANSEL and L. E. HUGHES, *University Department of Surgery, Welsh National School of Medicine, Cardiff*

The detailed surface anatomy of human subareolar breast ducts has been examined in a scanning electron microscope and correlated with the light microscopy appearances of adjacent sections. Normal ducts, obtained from 10 young, asymptomatic women undergoing reduction mammoplasty, were shown to possess numerous longitudinal folds and at high power the apices of the individual ductal cells were easily seen. Apocrine metaplasia was commonly present in these 'normal' ducts and appeared to be due to protrusion of the apices of the ductal cells.

A second group of dilated ducts obtained from 14 women undergoing duct resection for mammary duct ectasia was examined and compared with the 'normal' ducts. The surface ultrastructure of these ducts differed from normal in three respects: the longitudinal folds were flattened or absent, apocrine metaplasia was generally absent and the duct cells possessed smaller and less numerous surface microvilli. Ducts removed for inflammatory duct ectasia were lined by a 'carpet' of inflammatory cells lying on an intact epithelial surface. These observations lend support to the hypothesis (Bonser et al., 1961) that the primary defect of mammary duct ectasia is ductal inflammation, and that the dilatation is secondary to atrophy consequent upon the inflammation.

5. Macrophage/monocyte function in cancer patients

W. CANDLISH and J. BANCEWICZ, *Department of Surgery, Western Infirmary, Glasgow*

Macrophage/monocyte function may be important in cancer (Lauder, 1977), but there are few tests for clinical use. We have evaluated a new test that may measure phagocytosis of tumour cells (Halloran and Stylianos, 1978).

Antibody-coated tumour cells incubated with macrophages become resistant to lysis by complement. The degree of abrogation of complement lysis (ACL) may measure phagocytosis of the target cells. Mouse peritoneal exudate cells produced marked ACL (56·6±8·2 per cent) in a xenogeneic system. Effector cells adhered to plastic and were more efficient when activated by monolayer culture for 24 h. ACL did not occur at 4 °C and is therefore not simply a measure of binding to Fc receptors. Microscopic studies showed evidence of phagocytosis of tumour cells by macrophages in monolayer culture.

Peripheral blood mononuclear cells were obtained from human subjects by density gradient centrifugation. Adherent cells, after monolayer culture for 24 h, demonstrated ACL of xenogeneic tumour cells. Cryopreserved cells maintained their ability to mediate ACL.

In a small pilot study cryopreserved mononuclear cells from 3 healthy subjects and 6 patients with advanced cancer all demonstrated ACL of similar magnitude.

6. Surgical decision-making

C. V. RUCKLEY, J. B. P. FERGUSON, CONSTANCE CUTHBERTSON and DOROTHY LEIGHTON, *General Surgical Unit, Western General Hospital, Edinburgh*

When alternative levels of surgical care are available (e.g. minor outpatients, major day care, 5-day and main ward) the efficient use of resources necessitates accurate selection of patients in the outpatient clinic.

Health Service statistics are available concerning inpatients but there is no corresponding audit of outpatient clinics or operations. We have studied the decision-making process prospectively by analysing the entire hospital course of 2000 consecutive patients. The surgeon, when putting a patient on the waiting list, was asked to select the simplest grade consistent with satisfactory care, to forecast the duration of stay and to record the factors influencing the decision.

A total of 1049 patients (52 per cent) was put on the waiting list over a 10-month period: minor 361 (34 per cent), day care 87 (8 per cent), 5-day 315 (30 per cent), main ward 286 (28 per cent). To date, 666 have completed their hospital course and clinic follow-up. The main factor influencing the decision on choice of level was medical in 88 per cent, social 3 per cent, psychological 1 per cent, mixed 8 per cent. The selection of the level of care was accurate in that only 10 (1·5 per cent) had to be transferred to a level of care other than that chosen while 14 (2 per cent) had to be readmitted. The forecast of duration of postoperative stay was correct to the nearest day in 37 per cent, underestimated in 23 per cent and overestimated in 40 per cent.

We conclude that for a given surgical population it is possible to calculate quite precisely the scale of the various levels of care required. Forecasting of outcome can be sufficiently accurate to allow better use of surgical resources.

7. The appearance of endotoxin following urethral instrumentation

A. J. W. SIM and A. C. MCCARTNEY, *Departments of Urology and Bacteriology, Western Infirmary, Glasgow*

'Catheter fever' has been recognized as a complication of urethral instrumentation for many years (Mitchell et al., 1962). In an attempt to elucidate further the mechanism of this phenomenon we have studied 10 patients undergoing urethral instrumentation (9 cystoscopies and 1 urethral dilatation). Venous blood samples were taken before instrumentation, immediately after, half an hour after and hourly for 5 h. The samples were assayed for endotoxin using the Limulus amoebocyte lysate test, and cultured both aerobically and anaerobically. Before instrumentation mid-stream specimens of urine (MSSU) and urethral swabs were taken.

All patients were Limulus test negative (no endotoxin detected) before instrumentation. Immediately after 9 out of 10 were Limulus test positive (endotoxin detected) and the tenth was positive after an hour. Only 1 patient was Limulus test positive at 2½ h, but 6 out of 10 were positive at between 3½ and 5½ h. All blood cultures ($n = 80$) were sterile. Organisms were cultured from one MSSU and one urethral swab.

We have demonstrated that urethral instrumentation is associated with the appearance of endotoxin in the bloodstream and also that in some patients endotoxin reappears at a time when catheter fever characteristically occurs.

8. Management of postoperative pain

P. C. RUTTER, F. MURPHY and H. DUDLEY, *Academic Surgical Unit, St Mary's Hospital, London*

Reports (Fry, 1976; Leading Article, 1976) have suggested better control of postoperative pain by continuous opiate than by intramuscular administration. We undertook a double-blind trial to compare the two methods.

Forty-five patients with vertical abdominal incisions were given, after recovery of consciousness, a slow intravenous injection of morphine sulphate to a dose which relieved pain without overt respiratory depression. Over 72 h, and by random allocation, patients then received: 3·5 times the dose by continuous i.v. infusion (A); 12 times the dose by i.m. injection first 4-hourly and then 6-hourly (B_1); p.r.n. injections of the dose (B_2). Blinding between A and B_1 was achieved by i.m. or i.v. saline respectively; B_2 also received saline i.v. Subjects completed a linear analogue 12-hourly on their pain experience for the period. Vital capacity (VC) and peak expiratory flow rate (PEFR) were measured 12-hourly.

There was alway a significant difference (1 per cent, Mann–Whitney U test) on the analogue scale in favour of A against B_2. B_1 were intermediate between p.r.n. and i.v. but could not be statistically separated from either. VC and PEFR showed similar patterns.

	Hours postop.		
	24	48	72
Peak flow			
A	34	40	50
B_1	38	48	74*
B_2	46*	56*	63
Vital capacity			
A	28	37	50
B_1	33	41	53
B_2	42*	51*	60*

% of preoperative values (means).

* $P<0·05$ compared to A (Mann–Whitney U test).

Continuous i.v. infusion is the method of choice for postoperative pain relief with a minimum dose of opiate.

9. A comparison of pyloroplasty and pyloric ring dilatation as a drainage procedure for truncal vagotomy

N. LONGRIGG, J. GATELY, M. WISBEY and R. PRINGLE, *Department of Surgery, Ninewells Hospital, Dundee*

Forcible stretching (S) of the pylorus as an accompaniment to truncal vagotomy (TV) does not result in gastric stasis (Longrigg and Pringle, 1978). In view of the theoretical advantages of TV+S over TV+P (pyloroplasty), the present study was devised to compare these two operations.

Twenty-five patients with chronic duodenal ulceration had their liquid gastric emptying estimated after drinking 300 ml 15 per cent dextrose solution labelled with ^{99}Tc^{m} sulphur colloid. They were randomly allocated to either the TV+S (13) or TV+P (12) operation. Six months postoperatively the test was repeated and a clinical assessment made using a modified Visick grading.

The percentage emptying of dextrose solution at 5-min intervals was determined for each patient. The difference (D) between values for pre- and postoperative emptying was calculated for each interval, thus allowing a comparison to be made between the two operations using *t* test analysis. A greater value for D denotes increased emptying and, as can be seen in *Table I*, during the first 10 min the TV+S group empty at a significantly ($P<0·01$) slower rate than the TV+P group. This trend continues throughout the first hour.

Table I: DIFFERENCE BETWEEN PERCENTAGE OF MEAL REMAINING IN THE STOMACH PRE- AND POSTOPERATIVELY

Min. after drinking	TV+P	TV+S
5	42±5·9	15±3·4
10	51±5·8	35±9·7
25	42±2·8	29±7·9
45	30±3·9	20±4·3
65	21±4·7	3±8·5

All results are mean±s.e. mean.

Considering the overall clinical results (*Table II*), it is clear that as yet no obvious difference exists between the two operations.

Table II: VISICK GRADING OF FUNCTIONAL RESULTS 6 MONTHS AFTER OPERATION

	Visick grade			
	I	II	III	IV
TV+P	4	7	1	0
TV+S	6	5	2	0

In conclusion, the rapid gastric emptying of a liquid meal seen after TV+P is far less pronounced following TV+S, especially in the first 10 min. However, the clinical assessment at 6 months shows no obvious difference between the two operations.

10. Effects of somatostatin in duodenal reflux and the control state

W. E. G. THOMAS, *Department of Applied Physiology and Surgical Sciences, Royal College of Surgeons of England, Lincoln's Inn Fields, London*

Dogs with surgically produced duodenal reflux hypersecrete acid in response to pentagastrin, although the response to histamine is identical to the control response (Thomas, 1978). One explanation for this hypersecretion could be suppression of an inhibitory mechanism active against gastrin, but not to histamine. The effects of somatostatin were, therefore, studied in both dogs with duodenal reflux and control dogs.

Dose–response curves to an intravenous infusion of somatostatin were constructed using doses of 0·25, 0·5, 1·0, 2·0, 4·0 and 8·0 μg kg^{-1}h^{-1} with maximal background stimulation using pentagastrin 8·0 μg kg^{-1}h^{-1} or histamine 80 μg kg^{-1}h^{-}h^{1}. With 0·25 μg kg^{-1}h^{-1} of somatostatin, mean inhibition of pentagastrin-stimulated gastrin acid secretion was 54·6 per cent in the control group, but only 30·3 per cent in the reflux group ($0·02>P>0.01$ Mann–Witney U test), while at higher doses there was no significant difference. With histamine-stimulated gastric acid secretion the threshold dose of somatostatin for inhibition was 1·0 μg kg^{-1}h^{-1} with no significant difference between the two groups.

Dose–response curves to pentagastrin with a continuous infusion of 0·25 μg kg^{-1}h^{-1} somatostatin in dogs with duodenal reflux produced identical responses to those seen in control dogs with pentagastrin alone, thus abolishing the hypersecretion seen in the reflux group with pentagastrin alone. These results are consistent with somatostatin playing a role in an inhibitory mechanism that is suppressed in alkaline reflux.

THOMAS W. E. G. (1978) Gastric acid secretion studies in response to pentagastrin in duodenal reflux and bile diversion. *J. Physiol.* **281**, 36–37*P*.

11. Further studies on gastric fundic factor

SUZANNE RINNO BARMADA, K. BURDETT, J. B. ELDER and JACQUELINE BERRY, *Department of Medical Biochemistry and Department of Surgery, University of Manchester*

Recent studies (Elder and Lomas, 1977) have provided evidence for the release of a humoral substance from gastric fundic mucosa after alkalinization of the lumen. This factor was shown to reduce the absorption of the tracer ion ^{99}Tc^{m} and of glucose from the antrum in rabbits and conscious dogs. In order to investigate this phenomenon further, a rat bioassay was developed using ^{99}Tc^{m} in the antral or jejunal lumen, the absorption of tracer being monitored by counting samples of peripheral venous blood at 5-min intervals.

Intravenous infusion of a neutral gastric fundic extract or stimulation of the fundas by distension with air or stimulation by exposure to alkaline buffer (pH 8) all depressed the absorption of the tracer ion from the antrum (80 per cent reduction, $P<0·01$) and to a lesser extent from the jejunum (15–50 per cent reduction, $P<0·05$).

The effects are not reproduced by i.v. histamine (0 005 μg kg^{-1} min^{-1}), and do not appear to be due to a change in mucosal blood flow as measured by Sapirstein's method (Sapirstein, 1958).

Preliminary biochemical data indicate that the biological activity of the neutral fundic extract resides in a heat-stable, dialysable, small protein fraction with a molecular weight <10 000.

12. Does increased colonic motility affect colonic absorption?

A. GRANDISON, C. DARBY, J. HYLAND, R. SHIELDS and I. TAYLOR, *Departments of Surgery and Bioengineering, University of Liverpool*

The relationship between colonic motility and absorption is obscure. It is generally assumed that increased motility resulting in segmentation slows transit and hence allows extra time for absorption to take place (Wangel and Deller, 1965). Nevertheless, motor disorders of the colon are frequently associated with alternating constipation and diarrhoea. In this study the effect of increased colonic motility *per se* on absorption was determined.

Slow wave electrical activity was measured along the intact colon in 3 dogs and from Thiry–Vella loops in 3 dogs by serosal silver/silver chloride electrodes. Intraluminal pressure was simultaneously measured using thin, open-ended tubes. In each study two 20-min basal recordings were obtained and absorption of Na^{+}, Cl^{-}, H$_2$O, K^{+}, HCO$_3^-$ and HN$_3$ calculated. The colon was then stimulated for two 20-min periods using 6/min pulse waves (10 mA, 100 ms), during which time the absorption studies were repeated. Stimulation frequently produced forward pacing of the colon and significantly increased motility on each occasion (basal percentage motility 8·76 per cent ±2·06 s.e. mean, stimulation 41·31 per cent ±5·49 s.e. mean, $P<0·001$).

Increased colonic motility statistically significantly increased colonic absorption of Na^+, Cl^- and H_2O, irrespective of alteration in transit time. These data suggest that motor upsets in the colon may result in reduced stool weight without a change in transit time.

	Mean basal	Mean stimulation
Na^+ (μmol)	3·57	8·24*
Cl^- (μmol)	20·71	25·46*
H_2O (ml)	0·07	0·10*
K^+ (μmol)	−0·73	−0·99
HCO_3^- (μmol)	−6·42	−5·93
NH_3 (μmol)	7·51	8·16

* $P<0·01$.

All results = absorption cm^{-2} h^{-1}.

13. Carcinoma of the large bowel and faecal bile acids

D. G. MUDD, S. T. D. MCKELVEY, W. NORWOOD and D. T. ELMORE, *Departments of Surgery and Biochemistry, Queen's University, Belfast*

Faecal bile acid concentrations of patients with large bowel carcinoma were elevated in studies using enzymatic assay (Hill et al., 1975) or gas–liquid chromatography (Reddy and Wynder, 1977). Were these raised concentrations the result of the tumour rather than its cause?

Patients with large bowel carcinoma ($n=19$) were studied before operation and 10 were also studied 8–26 weeks postoperatively. They were compared with healthy controls ($n=19$) and with 20 patients who had undergone local excision of large bowel adenoma. Faecal 3-hydroxy bile acids were estimated enzymatically (Hill and Aries, 1971), omitting the reduction of the faecal extract with borohydride.

In cancer patients the preoperative bile acid concentration (26·3±2·5 μmol/g dry faeces; mean±s.e. mean) was not significantly different from that of controls (28·1±2·7) or adenoma patients (25·4±2·3). When the 10 cancer patients were compared preoperatively (26·8±3·3) and postoperatively (25·2±4·3), the difference in means was not significant. In 5 patients the bile acid concentration fell after surgery and in 5 it rose.

This study does not show the expected elevation of 3-hydroxy bile acids in patients with cancer of the large bowel nor does it suggest any consistent effect of surgery on faecal bile acid concentration.

14. Replacement of colonic mucosa by free and pedicled grafts of ileal mucosa in the dog

N. S. WILLIAMS, R. F. G. J. KING, A. H. SMITH and MARGARET SIMPSON, *University Department of Surgery, The General Infirmary, Leeds*

Radical surgery for ulcerative colitis usually means panproctocolectomy and ileostomy. Since ulcerative colitis is primarily a mucosal disease, several workers have recently concentrated on procedures which remove the diseased rectal mucosa and restore gastrointestinal continuity by replacing it with full-thickness ileum (Martin et al., 1977; Johnston and Williams, 1978). In an attempt to improve these techniques, we have explored the feasibility of replacing the colonic mucosa with grafts of ileal mucosa alone.

Both free and pedicled autografts of ileal mucosa were grafted into Thiry–Vella loops of colon which had been denuded of mucosa and submucosa.

All the free grafts failed to survive (7 dogs) and histological examination confirmed graft rejection. All the pedicled grafts (7 dogs) were successful and retained the histological characteristics of normal ileum.

Net transport and bidirectional movement of sodium, potassium and water were measured using a perfusion technique (Krejs et al., 1977) in 6 dogs with pedicled grafts and 4 control dogs with intact ileal loops.

Net movement	Controls ($n=4$)	Pedicled grafts ($n=6$)	P
Na^+ (μmol cm^{-1} h^{-1})	−57·1±10·8	48·2±13·5	<0·001
K^+ (μmol cm^{-1} h^{-1})	−0·5±0·5	+2·5±0·7	<0·05
H_2O (μl cm^{-1} h^{-1})	−436±69	+139±40	<0·001

Mean±s.e. mean.

A negative value denotes absorption and a positive value, secretion.

We conclude that the mucosa of the colon can be replaced successfully by grafts of ileal mucosa provided that an intact blood supply is preserved. The graft, however, ceases to function normally, and secretes Na^+, K^+ and water. These observations may be relevant to the conservative surgical treatment of ulcerative colitis.

15. Pathogenesis of water retention with intravenous nutrition: a prospective clinical study

R. C. SMITH, R. F. G. J. KING, A. H. SMITH, L. BURKINSHAW and G. L. HILL, *University Departments of Surgery, Nuclear Medicine and Medical Physics, The General Infirmary, Leeds*

Much of the weight gained by patients receiving intravenous nutrition is due to water retention. It is not known if this water accumulates inside or outside cells, and whether the retention is decreased by increasing the intravenous energy intake. In a prospective randomized study we measured changes in body composition (Hill et al., 1978) over a 14-day period in 16 patients who received 38·5±3·8 kcal kg^{-1} d^{-1} (group I) and compared these with the changes that occurred in 16 closely matched patients who received 53·5±5·0 kcal kg^{-1} d^{-1} (group II).

Group I patients lost body protein (−0·62±0·91 kg, $P<0·05$) although body weight (0·13±3·5 kg, n.s.), body fat (0·13±0·88 kg, n.s.) and body water (0·85±3·03 kg, n.s.) did not fall. Group II patients gained body weight (3·6±2·3, $P<0·001$), body protein (0·44±0·75 kg, $P<0·05$), body fat (0·80±0·96 kg, $P<0·01$) and body water (2·3±2·4 kg, $P<0·01$).

Half the patients in each group consented to muscle biopsy, which was analysed for water and electrolytes. The muscle water content is expressed as kg of intracellular water (ICW) and kg of extracellular water (ECW) per kilogramme of fat-free dry weight. The patient's own intracellular potassium concentration and total body potassium were used to derive whole body ICW and ECW.

Group I patients, who lost protein, demonstrated a reduction of ICW and an expansion of ECW. Group II patients, who

	Whole body		Muscle	
	ICW*	ECW*	ICW*	ECW*
Group I ($n = 8$)				
$\bar{x}$	−2·2	+3·4	−0·48	+0·54
s.d.	±1·5	±3·2	±0·41	±0·69
P	<0·01	<0·05	<0·01	n.s.
Group II ($n = 7$)				
$\bar{x}$	+1·5	+2·1	−0·12	−0·04
s.d.	±2·7	±4·3	±0·56	±0·91
P	n.s.	n.s.	n.s.	n.s.

* Expressed as kg/kg fat-free dry weight.

gained protein, had appropriate increases of both ICW and ECW. The results suggest that water retention in patients receiving intravenous nutrition occurs in the extracellular compartment and this can be decreased by increasing the intravenous energy intake.

16. A pocket calculator program for intravenous requirements

A. J. RICH, G. SHEARING and P. D. WRIGHT, *Department of Surgery and Computing Laboratory, University of Newcastle upon Tyne*

The provision of patients' daily requirements of fluid, electrolytes and nutrition is often made on a rule-of-thumb basis or using 'standard' regimens. Although acceptable for fit patients in the short term, this basis is unsatisfactory for those with prolonged fluid balance problems who require individual prescription.

Such calculation, although not difficult, is time-consuming; the recent marketing of card-programmable pocket calculators, however, has made the rapid estimation of individually tailored requirements possible.

A program was written to calculate water, electrolyte, calorie and nitrogen requirements from patients' measured fluid input and output and serum electrolyte concentrations. Inbuilt correction factors were included to account for unknown or unmeasured losses.

The composition of 'standard' 24-h regimens prescribed at the bedside was compared with the calculator estimation for 6 patients requiring parenteral nutrition. The percentage differences for each patient were calculated. In general, the 'standard' regimens tended to overestimate requirements of water and underestimate calcium, magnesium, calories and nitrogen, confirming the tendency of patients receiving parenteral nutrition to become overhydrated (Collins et al., 1978).

It is suggested that the advantage of individually tailored fluid therapy regimens can be extended to all patients by the use of a suitably programmed pocket calculator.

17. The value of early postoperative feeding with an elemental diet through a fine-needle catheter jejunostomy following major colorectal surgery

C. K. YEUNG, L. BURKINSHAW and G. L. HILL, *University Department of Surgery, The General Infirmary, Leeds*

It has been suggested that the infusion of an elemental diet in the period after major surgery minimizes nitrogen loss and is of clinical benefit (Sagar et al., 1978).

We conducted a prospective clinical trial to assess the nutritional benefits and clinical values of giving the elemental diet by continuous infusion through a fine-needle catheter jejunostomy during the first 14 days after major colorectal surgery. Twenty patients thus treated were matched with 20 control patients for sex, age, weight, degree of weight loss, diagnosis and operation. Body weight, arm muscle circumference (AMC) and total body potassium (TBK) were measured before and 2 weeks after surgery.

To date the results show that the technique of feeding postoperative patients through a fine-needle catheter jejunostomy is simple and practical. Our 20 patients received an average of 1650±284 kcal/d of the elemental diet over a mean time of 10·2±3·2 days. The elemental diet patients maintain their body weight and body cell mass (TBK) better than the control patients. However, the administration of the elemental diet is not associated with any demonstrable clinical benefit in terms of duration of postoperative hospital stay, abdominal wound healing and complication rate.

	Control ($n = 20$)	Elemental ($n = 20$)
Δ Body weight (kg)	− 26±0·4*	−0·6±0·4**
Δ TBK (mmol)	−283±36*	−61±43**
Δ Arm muscle circumference (cm)	− 0 8±0·2*	−0·3±0 2**

Results expressed as a mean±s.e. mean.
* Significant at 1% level.
** Not significant (paired *t* test).

18. Effect of different calorific doses of carbohydrate infusion on nitrogen excretion after surgery

A. RADCLIFFE, A. JOHNSON and H. DUDLEY, *Academic Surgical Unit, St Mary's Hospital, London*

The protein-sparing effect of low dose carbohydrate infusion in starving man (circa 6 kcal/kg bodyweight) was observed by Gamble in 1946 but the effect of variable high calorific regimens of carbohydrates without concomitant fat or nitrogen in postoperative patients is less well documented (Giddings, 1974; Long, 1977).

We have studied nitrogen excretion after surgery at three calorific levels—6, 25, 40 kcal of glucose kg^{-1} d^{-1} for the first 2 days postoperatively. There were 6 patients in each group having surgery of comparable severity (e.g. cholecystectomy, PGV). Urinary nitrogen was estimated by the Kjeldahl method. The results are shown in the Table.

	6 kcal	25 kcal	40 kcal
Day 1	0·24 ±0·07	0·15 ±0·09	0·15 ±0·04
Day 2	0·27 ±0·07	0·19 ±0·04	0·14 ±0·02

Nitrogen excretion in g/kg fat-free mass (mean ±s.d.).

Serum insulin levels were highest in the 40 kcal/kg group. Carbohydrate infusion has a progressive nitrogen-sparing effect quantitatively comparable to that achieved by intravenous amino acid infusion (Blackburn, 1977). If nitrogen-sparing is desired postoperatively, it can be achieved by the use of carbohydrate alone.

19. Is cholestasis in severely ill patients due to infection or malnutrition?

G. T. ROYLE and M. G. W. KETTLEWELL, *Nuffield Department of Surgery, University of Oxford, Radcliffe Infirmary, Oxford*

Intrahepatic cholestasis and abnormal liver function are common in severely ill patients. The cause is unknown, but factors, which often occur in combination, include parenteral nutrition, hypoxia, malnutrition and infection (Sitges-Creus et al., 1978). This study compared liver function in non-septic, malnourished patients, severely septic patients and patients recovered from sepsis with that in healthy control subjects of similar age and sex. No patients had received parenteral nutrition.

Table I: COMPARISON OF THE GROUPS

	C ($n = 10$)	M ($n = 7$)	S ($n = 10$)	S-r ($n = 4$)

GOT (i.u./l)	46±11	48±13	70±12**	25±7
Urea (mmol/l)	4·6±0·5	5·0±1·0	4·8±0·8	4·3±1·1

C, control; M, malnourished; S, septic; S-r, septic, recovered. All mean±s.e. mean. * $P<0·05$; ** $P<0·02$; *** $P<0·001$ compared with control.

Septic patients, unlike malnourished subjects, had decreased plasma concentrations of albumin and cholesterol and increased concentrations of bilirubin, alkaline phosphatase and GOT compared with control subjects. Following clinical recovery from infection, liver function tests returned to normal though weight loss was still evident several weeks later. These results suggest that abnormal liver function and cholestasis result from infection rather than from malnutrition. Infection should be carefully sought in patients receiving parenteral nutrition who develop abnormal liver function.

20. The maximum activity of three key enzymes in human skeletal muscle and the effects of a course of intravenous nutrition

R. F. G. J. KING, R. C. SMITH, C. K. YEUNG, R. ELLIS and G. L. HILL, *University Department of Surgery, The General Infirmary, Leeds*

It is not known if fundamental alterations in the maximum activity (MA) of Kreb's cycle and glycolysis occur in critically ill patients and whether these pathways are influenced by intravenous nutrition. It has been shown in both vertebrates and invertebrates (Crabtree and Newsholme, 1972; Read et al., 1977) that the MA of α-ketoglutarate dehydrogenase (α-KGD-ase) and phosphofructokinase (PKF) represent the MA of these pathways *in vivo*.

We have studied the MA of these enzymes in chopped skeletal muscle and also the MA of fructose 1,6-diphosphatase (FDPase) as an indicator of substrate cycle activity in 9 critically ill patients before and after intravenous nutrition and in 12 control subjects. The results were as follows:

	α-KGDase*	PFK*	FDPase*
Surgical pre. IVN (1)	0·68±0·13	17·9±2·1	0·57±0·10
Surgical post. IVN (2)	0·75±0 06	20·7±1·2	0·45±0·04
Control (3)	0·86±0·09	23·9±1·9	1·31±0·16
P 1 *v.* 2	n.s.	n.s.	n.s.
P 1 *v.* 3	n.s.	n.s.	<0·02
P 2 *v.* 3	n.s.	n.s.	<0·01

Values for MAs are mean±s.e. mean.
* μmol min^{-1} g muscle^{-1}.

There were no significant differences in the mean MA of α-KFDase and PFK in the muscle of patients before or after intravenous nutrition and between the patients and controls. However, the mean MA of FDPase was significantly less in the patients.

It is conlcuded that the MA of both Kreb's cycle and the glycolysis is not impaired either before or after intravenous nutrition. However, since FDPase was significantly lower both before and after intravenous nutrition the possibility exists that the kinetics of glucose flow are altered within skeletal muscle in these patients.

21. Surgeons heart rates and surgical performance: a double-blind trial of oxprenolol

G. E. FOSTER, D. F. EVANS, CAROL MAKIN and J. D. HARDCASTLE, *Department of Surgery, University of Nottingham*

Surgeons experience a tachycardia during operating which is abolished by β-blockade (Foster et al., 1978). We report a prospective double-blind trial in which senior registrars and consultants took 40 mg oxprenolol or a matching placebo before four operating lists. During one case in each list, three tests of surgical performance were made. Suturing accuracy was assessed using a method which required ten sutures to be placed 1 cm apart. Tremor was measured during the passage of a curved needle through a series of graded holes using an electronic contact counter. Concentration and reaction time over a 2-min period were assessed using the 'four choice' test (Wilkinson and Houghton, 1975). Heart rates were recorded throughout operating sessions using the medilog ambulatory system. After each list, surgeons completed visual analogue scores summarizing their subjective feelings and were asked which medication they had taken.

During the operations after oxprenolol, heart rates averaged 83 (±8·1 s.d.) per minute for all surgeons, and after placebo 120 (±10·5 s.d.) per minute (paired $t = 7·5$, $P<0·001$). In the tests of tremor and suturing accuracy, there was no difference between the oxprenolol and placebo groups, but reaction time was slower for each surgeon ($P<0·01$) for the oxprenolol group. The tests showed consistency for each surgeon. Subjective feelings were not affected by either preparation but surgeons were surprisingly unaware that they had taken oxprenolol.

22. The use of cooled irrigating fluid for transurethral resection of the prostate

A. E. KULATILAKE, P. ROBERTS, D. F. EVANS and J. WRIGHT, *Department of Surgery, University of Nottingham*

Cockett et al. (1961) reported no difference in blood loss during transurethral resections of the prostate using cooled irrigation fluid (3 °C) compared with fluid at ambient temperature. Conversely, Serrao et al. (1976) reported that cooling of the irrigation fluid to 2 °C reduced both blood loss at operation ($P<0·001$) and irrigant volume ($P<0·002$).

Forty patients were randomly divided into two groups before transurethral resection of the prostate. In the first group ($n = 20$) the irrigation fluid was cooled to 8 °C, the lowest temperature at which the resectoscope could be comfortably held, and in the second ($n = 20$) the fluid was at ambient temperature.

Irrigation fluid was maintained at a constant temperature by passing it through a heat exchanger in a cooled water bath. We monitored the fluid temperature as it entered the resectoscope and the oesophageal temperature of the patient. We also measured the volume of irrigation fluid used, the blood loss both during and after resection and the weight of resected tissue.

The parameters measured covered a wide range of values and non-parametric analysis was used to analyse the results. Significantly lower volumes of cooled fluid were required during transurethral resection of the prostate (Mann-Whitney U test, $P<0{\cdot}002$), and the clarity of the operative field was improved.

These results suggest that advantages may be gained by the use of cooled irrigation fluid during routine transurethral resection of the prostate.

23. The behaviour of antibiotics in bone cements

W. R. QUINLAN, *Department of Surgery, University College, Dublin*

This paper describes an original study of the behaviour of the antibiotics diethanolamine fusidate (Fucidin), diethanolamine fusidate and erythromycin, clindamycin, cephazolin sodium (Kefzol) and gentamicin, when mixed with each of the bone cements CMW, Palacos, Simplex and Sulfix.

Each antibiotic bone cement combination was inserted into the reamed medullary canal of one femur of each of 5 live rabbits. A metal cannula with side-wall perforations was placed at each cement bone interface, with its proximal end lying subcutaneously. Using normal saline, percutaneous lavage through the cannulas was carried out at regular intervals postoperatively. The lavage fluid was assayed for antibiotic activity, using the appropriate test organisms. Duration of release, in days is shown.

Cement	DF	DF+E	C	CS	G
CMW	140±20	16±3	14±4	8±3	79±20
Palacos	73±15	30±20	6±3	13±3	56±20
Simplex	56±7	31±14	24±7	7±3	75±12
Sulfix	50±20	14±10	7±3	15±3	54±20

DF, Diethanolamine fusidate; DF+E, diethanolamine fusidate+erythromycin; C, clindamycin; CS, cephazolin sodium; G, gentamicin.
All results mean±s.e. mean.

These results suggest that CMW, Palacos and Simplex are satisfactory antibiotic carriers. Release levels of cephazolin sodium and clindamycin were short-lived but high. Clinical experience in the prophylaxis against infection in joint replacement has not yet shown whether this is desirable.

Immunological tolerance of the various antibiotic cement combinations was investigated by intradermal injections of dilutions of the antibiotics. Assessment by skinfold measurements and by clinical appearance showed no evidence of allergy development. Liver and kidney biopsies showed no signs of cumulative antibiotic toxicity.

24. Peritoneal fibrinolysis and adhesion formation

A. T. RAFTERY, *University Department of Surgery, Manchester Royal Infirmary*

The pathogenesis of intraperitoneal adhesions is poorly understood. As part of the initial response to injury, fibrin is deposited on serosal surfaces resulting in a fibrinous adhesion. Prevention of the development of fibrous adhesions depends on the removal of this fibrin before it is invaded by fibroblasts.

A quantitative technique (Raftery, 1977) has been used to measure the fibrinolytic activity in healing unsutured peritoneal defects in rats. These defects heal with little or no adhesion formation. Fibrinolytic activity is lowest at 24 h and thereafter increases, until at 8 days, when peritoneal healing is complete (Raftery, 1973), it is still greater than that of normal peritoneum. Peritoneal fibrinolytic activity has also been measured following four other types of peritoneal insult; diathermy wounds, free peritoneal grafts, ischaemic bowel and bile peritonitis. The degree of reduction of peritoneal fibrinolytic activity has been compared with that of the unsutured peritoneal defect, and has been correlated with the incidence of adhesions. The results are shown in the Table. Normal peritoneum has a fibrinolytic activity of 0·075±0·006 Ploug units.

Insult	Lowest recorded FA*	Incidence of adhesions
Unsutured defect	0·036±0·005	5%
Free graft	0·013±0·009 ($P<0{\cdot}01$)	100%
Diathermy	0 ($P<0{\cdot}001$)	95%
Ischaemic bowel	0·009±0·005 ($P<0{\cdot}001$)	100%
Bile peritonitis	0·033±0·014 ($P>0{\cdot}5$)	0%

* FA, Fibrinolytic activity in Ploug units, mean±s.d.

Adhesions occur in areas where peritoneal fibrinolytic activity is significantly reduced. The results suggest that fibrinolytic agents may be beneficial in the prophylaxis of adhesions.

25. The effect of prophylactic cotrimoxazole on postoperative pulmonary complications

C. MORRAN and C. S. MCARDLE, *Departments of Surgery, Royal Alexandra Infirmary, Paisley and Victoria Infirmary, Glasgow*

Pulmonary complications following biliary surgery are common. Chest infection is usually associated with the presence of *Haemophilus influenzae* or *Streptococcus pneumoniae* in the sputum; both organisms are sensitive to cotrimoxazole. A controlled study was undertaken to assess the value of prophylactic cotrimoxazole in reducing these sequelae.

Sixty-eight consecutive patients undergoing elective cholecystectomy were randomized to receive either a single preoperative dose of cotrimoxazole or a placebo. Postoperative pulmonary complications were assessed using clinical criteria. Arterial blood-gas analysis was undertaken preoperatively and on days 1–4 postoperatively.

Thirty-six patients had no clinically significant postoperative pulmonary complications; 18 developed atelectasis and 14 chest infection. The pattern of arterial oxygen tensions in patients with pulmonary complications was significantly different from that in the uncomplicated group (Table). *H. influenzae* and *S. pneumoniae* were present in 8 of the 14 patients with chest infection.

	Arterial oxygen tensions†			
	Postop. day			
Group	1	2	3	4
No postoperative complications	83±2	85±2	87±2	93±2
Atelectasis	75±3*	78±3*	82±2	87±3
Chest infection	73±3**	70±3***	71±2***	75±3***

† Expressed as a percentage of preoperative value.
* $P<0{\cdot}05$; ** $P<0{\cdot}005$; *** $P<0{\cdot}001$.

Eleven of the 34 control patients developed chest infection, whereas only 3 of 34 patients receiving cotrimoxazole developed chest infection ($P<0{\cdot}05$).

These data suggest that a single prophylactic dose of cotrimoxazole significantly reduces respiratory morbidity following biliary surgery.

26. What patients recall of an intensive care unit

B. W. ELLIS, BARBARA HOGGART, JOSEPHINE WITHEY, KIM DONAGHUE and JENNIFER JONES, *Academic Surgical Unit and Department of Anaesthesia, St Mary's Hospital, London*

One hundred consecutive patients were interviewed between the third and seventh days following their discharge from an intensive care unit. Their mean stay was 40 h (range 7–120).

The patients' recall of events was generally poor. Forty per cent were able to give a fair estimate (<50 per cent error) of the duration of their stay, while 20 per cent were unable to estimate at all or had no recollection of the unit.

Only 7 of 22 patients treated by assisted ventilation were able to recall the experience.

Ninety-three patients were able to comment on their recollection of nursing and medical staff. Of these 21 said they were given insufficient explanation, 17 that medical staff were 'not around when needed' and 7 that worrying details were discussed around their bed.

Of the factors provoking anxiety and worry, 32 patients complained of pain, 18 of lack of sleep and 18 of physiotherapy.

Factors that prevented or disturbed sleep were: inability to be comfortable, 55 patients; pain, 41; anxiety, 18; and the wearing of a mask, 17 patients.

Less than half of the patients said they were pleased to return to a general ward.

27. A randomized trial to compare oral with parenteral antibiotic prophylaxis in elective colonic resection

Y. ARABI and M. R. B. KEIGHLEY, *The General Hospital, Birmingham*

A prospective randomized trial has compared oral ($n = 39$) with parenteral prophylaxis ($n = 42$) in elective colonic resection for malignant disease. Patients received metronidazole and kanamycin. Oral therapy was designed to reduce the bacterial flora of the colon (Goldring et al., 1975) without achieving therapeutic serum concentrations and systemic prophylaxis to provide adequate serum levels without altering the colonic microflora. Serum and colonic contents were sampled at operation for antibiotic assay and for counts of pathogenic bacteria in the colon. All patients with postoperative diarrhoea were investigated for faecal toxins and *Clostridium difficile* (George et al., 1978).

Oral preparation significantly reduced the counts of *Escherichia coli* (10^7 to 10^4) and *Bacteroides fragilis* (10^8 to 10^1) in the colon and did not achieve therapeutic serum levels. Nevertheless, high counts of resistant bacteria were observed in 14 (36 per cent) of the orally prepared patients. Intravenous prophylaxis achieved therapeutic serum levels but had no influence on colonic microflora. The overall rate of sepsis was 33 per cent in patients prepared orally compared with 11 per cent in patients receiving parenteral prophylaxis ($P < 0{\cdot}02$). Pseudomembranous colitis occurred in 6 patients receiving oral preparations but in none receiving systemic antimicrobials.

These results indicate that parenteral antibiotic prophylaxis is more effective at reducing sepsis and is less likely to be complicated by antibiotic resistance and pseudomembranous colitis than oral antimicrobial bowel preparation.

28. The measurement of gastric emptying: a comparison of fixed scintillation detection and the double sampling technique

G. BLAKE and S. T. D. MCKELVEY, *Department of Surgery, Queen's University, Belfast*

The emptying of fluid meals can be accurately measured using a nasogastric tube (George, 1968; Hunt and Knox, 1968). Fixed scintillation detection has been shown to give similar information to external scanning using a gamma camera (Ostick et al., 1976), but has not been compared with intubation techniques.

The double sampling technique was compared with fixed scintillation detection in 14 normal subjects and in 15 patients who had had a vagotomy and drainage procedure. The 500-ml fluid meal contained emulsified milk, lactose and water. Double sampling using ^{51}Cr and scintillation detection using ^{113}In were performed simultaneously.

The times required to achieve 50 per cent emptying were compared. In normal subjects, both methods correlated well (Wilcoxon matched pairs test: $P < 0{\cdot}05$; Spearman's rank correlation coefficient: $r_s = 0{\cdot}856$). In operated subjects, rapid emptying of the initial part of the meal occurred. This caused problems in measurement, as scintillation detection readings are based on the initial reading following ingestion of the meal. This problem was overcome by relating all readings to an *in vitro* measurement of the meal to a 'water phantom' leading to good correlation at 50 per cent emptying (Wilcoxon: $P > 0{\cdot}05$; $r_s = 0{\cdot}625$).

The study of emptying of fluid meals gives more information about post-vagotomy syndromes than the study of mixed meals. External detection methods require modification when used in this situation.

29. Bile acids and colonic myoelectrical activity

M. FLYNN, C. DARBY, P. HAMMOND, J. HYLAND and I. TAYLOR, *Departments of Surgery and Bioengineering, University of Liverpool*

The cathartic property of bile acids can be explained by their inhibitory action on colonic absorption (Mekhjian and Phillips, 1971), but whether they alter motility and thereby influence colonic motor disorders by a similar pathway is not known.

In this study the effect of different concentrations of cholic, deoxycholic and chenodeoxycholic acid on colonic myoelectrical activity was recorded in four dogs. Slow wave electrical activity was measured using chronically implanted silver/silver chloride electrodes and intraluminal pressure simultaneously recorded with thin, open-ended tubes.

Measurements were obtained during a control period and following separate instillations of 5-mmol, 10-mmol and 15-mmol aliquots of each bile acid.

There was no statistically significant difference in percentage motility, motility index or basal pressure with either cholic or chenodeoxycholic acid. Deoxycholic acid (15 mmol), however, resulted in a marked increase in percentage motility on each occasion (control: median 4·1 per cent, range 0–23 per cent; after instillation: median 27 per cent range 20·6–45 per cent; $P < 0{\cdot}001$). This was accompanied by an increase in spike activity but no alteration in mean slow wave frequency. Cholestyramine inhibited the motor response. All concentrations of each bile acid inhibited Na, K and H_2O absorption.

Hence, only deoxycholic acid affects both colonic motility and absorption, presumably by different pathways, and may thus assume importance in the aetiology of colonic motor disorders.

MEKHJIAN N. and PHILLIPS S. (1971) Colonic secretion of water and electrolytes induced by bile acids. *J. Clin. Invest.* **50**, 1569–1572.

30. Extent of spread of a steroid-containing foam after intrarectal administration

D. J. HAY, H. SHARMA, B. PULLEN and M. H. IRVING, *University Department of Surgery, Hope Hospital, Salford, and Department of Medical Biophysics, Manchester University*

A steroid-containing foam (Colifoam) is currently being marketed for the local treatment of ulcerative colitis. It contains hydrocortisone acetate 10 per cent. Whilst steroid enemas are believed to spread to the splenic flexure (Flavell Matts, 1960) there is as yet no information on how far the foam spreads.

A standard dose of Colifoam was labelled with technetium ($^{99}Tc^{m}$ 100 μCi), which was adsorbed on to microspheres of Amberlite resin (200 mesh) distributed through the foam. Preliminary studies show the spread of radioactivity within the foam to be even. The labelled dose was given to 12 subjects, 4 with known ulcerative colitis and 8 subjects with normal bowel habit. The subjects were scanned with a gamma camera after 15 min, 2 h and 4 h; between scans the subjects were mobile.

Considerable variation was observed in the immediate spread of foam after its administration (9·1 cm±s.d. 3·7). No significant further spread of the foam was observed at 2 h and 4 h following administration. There was no difference in the behaviour of the foam control subjects and those with colitis.

These results show that whilst there is considerable variation in the immediate spread of the foam following administration there is no significant further spread with time and it is doubtful if the foam ever leaves the rectum.

FLAVELL MATTS S. G. (1960) Local treatment of ulcerative colitis with prednisolone-21-phosphate enemata. *Lancet* 1, 517–519.

31. The effect of highly selective vagotomy and truncal vagotomy on the lower oesophageal sphincter

J. G. TEMPLE, R. J. R. GOODALL, D. J. HAY and D. MILLER, *Department of Surgery, Hope Hospital (University of Manchester School of Medicine), Salford*

Significant gastro-oesophageal reflux often occurs after truncal vagotomy and drainage and this may be due to shortening of the lower oesophageal pressure zone (LOPZ) postoperatively (Thomas and Earlam, 1973). A 25 per cent incidence of gastro-oesophageal reflux has been reported following highly selective vagotomy (Temple and McFarland, 1975), but evidence of incompetence of the LOPZ after this operation is lacking.

The length and resting pressure produced by the LOPZ was measured by manometry using the station pullthrough technique in two groups of subjects:

1. Nineteen healthy volunteers who had no evidence of upper gastrointestinal disease (normal group).
2. Twenty patients studied immediately before and 3 months after surgery for duodenal ulceration, 14 having had a PGV and 6 having had a TV+P.

Before operation, the length and pressure of the LOPZ in patients with a duodenal ulcer were similar to the normal group (Table). Postoperatively, no significant change was produced in either the length or pressure of the LOPZ by either PGV or TV+P.

We conclude that gastro-oesophageal reflux following PGV or TV+P is not related to surgically induced incompetence of the lower oesophageal sphincter as measured by either the length or resting pressure of the LOPZ.

		Duodenal ulcer ($n = 20$)		
			Postop.	
LOPZ	Normal ($n = 19$)	Preop.	PGV ($n = 14$)	TV+P ($n = 6$)
Pressure (mmHg±s.d.)	10·4±5·5	8·8±3·6	9·0±3·5	11·1±3·9
Length (cm)	3·4±0·5	2·9±1·1	3·1±0 8	3 2±0·5
